Vegetable Brassicas

Mary C. Christey and Robert H. Braun

New Zealand Institute for Crop and Food Research Limited, Christchurch, New Zealand

1. INTRODUCTION

The Brassicaceae family contains about 3000 species in 350 genera including many important vegetable species such as water cress (*Nasturtium officinale*), garden cress (*Lepidium* spp.), radish (*Raphanus sativus*), horse radish (*Armoracia lapathifolia*), roquette (*Eruca sativa*), sea kale (*Crambe maritima*), and many ornamental species such as *Matthiola* and *Malcolmia* (stocks), *Iberis* (candytuft), and *Alyssum*. In addition, the Brassicaceae family includes the economically important *Brassica* genus, which consists of about 85 species including several important vegetables. In addition to many important vegetable species, the Brassicaceae family includes condiment producing plants such as the common horseradish (*Armoracia*), Japanese horseradish (*Wasabi japonica*), and mustard (*Brassica*); forage crops such as turnip, swede, rape, kale (all *Brassica* spp.); and important oilseed plants such as rape and turnip (*Brassica*) and *Crambe* (Bailey and Bailey, 1976). Turnips and swedes provide winter fodder for sheep and cattle. In New Zealand, arable Brassica crops have been important for animal production since 1870. They are used to supplement pasture for sheep and cattle when pasture growth is not sufficient (Palmer, 1983). *B. oleracea* originated in southern Europe, where it grows along the coasts of the Mediterranean Sea (Nieuwhof, 1993).

The six cultivated *Brassica* species are interrelated with the three amphidiploids (*B. napus*, *B. juncea*, and *B. carinata*) arising from interspecific

hybridization between the three diploid species (*B. oleracea*, *B. nigra*, and *B. rapa* (syn. *B. campestris*) (U, 1935). Genome size, as determined by flow cytometry by Arumuganathan and Earle (1991), ranges from 600 to 662 Mbp (mega base pair) for the haploid C genome of *B. oleracea*. The A genome of *B. rapa* Pak choi is smaller (507 Mbp).

Vegetable Brassicas are economically important and grown worldwide for consumption as both fresh and frozen produce. The major group of Brassica vegetables are members of *B. oleracea* ($n = 9$), which is a polymorphic species consisting of 14 varieties, distinguished by variations in internode length, stem swelling, axillary bud development, foliage curling, and inflorescence development. *B. oleracea* is an important source of vegetables in the Brassicaceae with practically every part of the plant utilized including the leaves (cabbage, kale, collards), terminal buds (early cauliflower), axillary buds (Brussels sprouts), stems (kohlrabi), floral primordia (late cauliflower), and flower buds (broccoli). Other vegetable members are present in *B. rapa* where it is the leaves (Chinese cabbage) and swollen hypocotyl (turnip) that are utilized.

Vegetable Brassicas are highly nutritious, particularly broccoli, which contains high amounts of calcium, carotene, vitamin C, and vitamin A. In addition, vegetable Brassicas are gaining in popularity as they contain compounds with anticancer properties. Worldwide, cabbage is the most commonly grown vegetable Brassica with over 3 million hectares grown in 2005. The main area of vegetable Brassica production is in China where 1.5 Mha was grown in 2005. India, Russia,

and Asia in general are also important areas of vegetable production. Cauliflower is also an important vegetable Brassica with approximately 857 000 ha grown worldwide. In 2003, 16 million tons of cauliflower were produced worldwide with China and India accounting for 75% of this figure (<http://www.FAO.org>). In developing countries, Brassica crops, such as cabbage, cauliflower, kale, mustard, are important food plants. In India, for example, cabbage and cauliflower are grown by more than 20 million small-holding farmers, over 250 000 ha of land, or over more than 10% of the total area devoted to vegetable production (<http://www.CIMBAA.org>). India is the world's largest cauliflower grower and second largest cabbage grower (after China). Cabbage and cauliflower are important in the diets in this country where vegetarianism is widespread. The one and a half million cabbage and cauliflower fields occupy 440 000 ha in India with a production of 6.4 million tons annually (<http://www.CIMBAA.org>).

In recent years, the development of plant transformation procedures has enabled the genetic modification of many crop plants, including *Brassica* species. Transformation protocols have been developed for a wide range of members of the Brassicaceae family, with the major emphasis on the economically important oilseed rape *B. napus*. Development in this crop, particularly in Canada, has progressed to the stage where herbicide resistant genetically modified (GM) *B. napus* are grown over wide areas. Use of *Agrobacterium tumefaciens*-based transformation methods are by far the most efficient for use with most vegetable Brassicas and have been successfully used to produce transgenic plants of several other vegetables. In this chapter, we summarize the results obtained with the introduction of traits covering a range of characteristics including introduction of pest and disease resistance, altered postharvest attributes and alteration of flowering and breeding systems.

2. DEVELOPMENT OF TRANSGENIC VEGETABLE BRASSICAS

2.1 Transformation Methods

Vegetable Brassicas are susceptible to attack from several insect pests and to infection by a range

of bacterial and fungal diseases. In addition, postharvest deterioration can limit shelf life. Genetic engineering (GE) technology offers the opportunity to produce pest- and disease-resistant varieties by enabling transfer of genes that could not be possible by conventional breeding methods. An advantage of GE is that a small amount of well-characterized DNA can be quickly added into the genetic background of the elite lines. This DNA can be from any source; plant, animal, bacterial, viral, or artificially synthesized. Since the first reports of transgenic vegetable Brassicas in the late 1980s, GE of vegetable Brassicas has now progressed to the stage where agronomically useful traits have been introduced and numerous plants have been field tested. However, no commercial release of a transgenic vegetable Brassica cultivar has yet occurred.

2.1.1 *Agrobacterium*

Agrobacterium-based methods are the most widely used approach for producing transgenic vegetable Brassicas and have been used to produce transgenic plants in most vegetable types (Table 1). Binary vectors based on the nopaline strain LBA4404 are the most commonly used *Agrobacterium* strain followed by EHA101 (reviewed in Christey and Braun, 2004). The prerequisites for efficient production of transgenic plants are susceptibility to *Agrobacterium* and an efficient shoot regeneration system. Previously, we have reviewed ways to increase transformation rates by consideration of the culture conditions and genetic factors (Christey and Braun, 2004).

In addition to susceptibility to *Agrobacterium*, an efficient shoot regeneration system is required for the successful application of *Agrobacterium*-mediated transformation for the introduction of agronomically important genes. High rates of shoot regeneration have been reported from many vegetable Brassicas from many explant sources. *B. oleracea* vegetables are particularly amenable to *in vitro* manipulation as shoot regeneration has been demonstrated for 13 types from a number of different vegetative explants and also from reproductive or floral organs (reviewed in Christey and Braun, 2004). In addition to explant source, choice of cultivar is important for achieving high rates of shoot regeneration as demonstrated by

Table 1 Summary of traits transformed into vegetable *Brassicas*^(a)

the detailed studies on the effect of cultivar on regeneration ability in cauliflower (Bhalla and Smith, 1998b) and cabbage (Kuginuki and Tsukazaki, 2001).

B. campestris explants are more recalcitrant to shoot regeneration than *B. oleracea*, but the use of ethylene inhibitors has been beneficial. Chi and Pua (1989) improved shoot regeneration rates from cotyledons of *B. campestris* ssp. *chinensis* (Chinese cabbage) through the addition of the ethylene inhibitors AgNO₃, Ag₂SO₄, or aminoethoxyvinylglycine (AVG). Explant source and age were also important factors influencing shoot regeneration as 3-days-old cotyledons showed higher shoot regeneration than 5-days-old explants and hypocotyl explants showed rare shoot regeneration. Shoot regeneration from cotyledons and hypocotyls of recalcitrant *B. campestris* comprising ssp. *chinensis*, ssp. *parachinensis*, and ssp. *pekinensis* was also markedly enhanced by the presence of either AgNO₃ or AVG, though in some cases AVG was inhibitory at high concentration (Chi *et al.*, 1990). Palmer (1992) also found that AgNO₃ enhanced both the percentage shoot regeneration and the number of shoots per explant from *B. campestris* cotyledon explants.

Ethylene inhibitors are also beneficial for regeneration from *B. oleracea* explants. Sethi *et al.* (1990) studied the effect of ethylene inhibitors on ethylene level and on shoot regeneration from cauliflower hypocotyl explants. They found that AVG, CoCl₂, and AgNO₃ induced higher rates of shoot regeneration, with reduced ethylene level, compared to controls. de Block *et al.* (1989) found that AgNO₃ was important for efficient shoot regeneration in cauliflower. Ding *et al.* (1998) obtained a significant improvement in shoot regeneration from cauliflower hypocotyl explants when the explants were pretreated with callus-inducing medium for 3 days, followed by supplementing the regeneration medium with silver ions.

In addition, Gapper *et al.* (2002) noted that transformation of broccoli with an anti-sense 1-aminocyclopropane-1-carboxylate synthase (ACC) oxidase gene significantly increased transformation rates with cotyledon petioles, but not with hypocotyl explants. They attributed the increase in transformation rate to an ethylene biosynthesis blocking effect.

2.1.1.1 *A. tumefaciens*-mediated transformation

The most common method used for vegetable Brassica transformation involves *A. tumefaciens* with all major vegetable types being successfully transformed by this method. However, transformation efficiencies are low, usually less than 5% (reviewed in Christey and Braun, 2004). Seedling explants, such as hypocotyls or cotyledonary petioles, are the most common explants used. Recent developments in *A. tumefaciens*-mediated transformation are summarized in Table 1 and indicate that a range of traits of agronomic importance have been introduced into vegetable Brassicas.

2.1.1.2 *A. rhizogenes*-mediated transformation

A. rhizogenes is a soil bacterium responsible for the development of hairy root (HR) disease on a range of dicotyledonous plants. Transgenic plants have been obtained after *A. rhizogenes*-mediated transformation in 89 different taxa, representing 79 species from 55 genera and 27 families (reviewed in Christey, 2001). Co-cultivation of explants with *A. rhizogenes* results in the production of HRs that are easily distinguished by their rapid, highly branching growth on hormone-free medium and plagiotropic root development. Root tips are then transferred to callus induction media for shoot regeneration, though regeneration may also occur spontaneously.

A. rhizogenes-mediated transformation has been used to obtain several transgenic vegetable Brassicas including broccoli, cabbage, cauliflower, Chinese cabbage, and Brussels sprouts (reviewed in Christey and Braun, 2004). Overall, rates of transformation are low, but in some cases, transgenic vegetable Brassicas were more efficiently obtained via *A. rhizogenes*-mediated transformation than *A. tumefaciens* (Christey *et al.*, 1997). In most cases, gene transfer involves marker and/or reporter genes, but genes of agronomic use that have been introduced include reduced ethylene production and resistance to the herbicide Basta (reviewed in Christey and Braun, 2004).

One disadvantage of *A. rhizogenes*-mediated transformation is that once transgenic root

cultures are obtained, shoots still need to be regenerated. In addition, plants regenerated from HRs often exhibit an altered phenotype characterized by several morphological changes including wrinkled leaves, shortened internodes, reduced apical dominance, reduced fertility, and altered flowering time and plagiotropic roots (Christey, 2001). These characteristic phenotypic changes are due to the transfer and expression of four loci (*rolA*, B, C, D) located on the TL-DNA. However, several studies have shown segregation of root inducing (Ri) and tumor inducing (Ti) transfer-DNA (T-DNA) and therefore the recovery of phenotypically normal transgenic plants (Christey *et al.*, 1999; Puddephat *et al.*, 2001).

2.1.2 Direct uptake into protoplasts

While *Agrobacterium*-mediated transformation is the most common method to obtain transgenic vegetable Brassicas, other methods have also successfully been used. Vegetable Brassicas are amenable to regeneration from protoplasts (Chen *et al.*, 2004b; reviewed by Christey, 2004), thus direct DNA uptake into protoplasts is a feasible alternative for the production of transgenic plants. However, despite the fact that shoot regeneration has been established from protoplasts of numerous vegetable Brassicas at high efficiencies for several years, reports of protoplast-mediated transformation are rare. Eimert and Siegemund (1992) co-cultivated cauliflower protoplasts with *A. tumefaciens* and obtained kanamycin resistant calli but only rarely shoots did develop further.

Mukhopadhyay *et al.* (1991) reported an efficient system using polyethylene glycol (PEG)-mediated DNA uptake into cauliflower hypocotyl protoplasts. Large numbers of fertile transgenic plants were produced. Eimert and Siegemund (1992) used PEG-mediated and/or electroporation of cauliflower mesophyll protoplasts but only a few shoots were obtained. Radchuk *et al.* (2002) studied the effect of a range of factors on PEG-mediated direct DNA uptake into cauliflower mesophyll protoplasts. Fertile transgenic plants were obtained with either kanamycin or hygromycin resistance. More recently, Nugent *et al.* (2006) have used PEG-mediated DNA uptake into cauliflower mesophyll protoplasts to obtain

transgenic plants expressing β -glucuronidase (GUS) and hygromycin resistance.

2.1.3 Microprojectile acceleration

Particle gun transformation involves firing small DNA-coated microprojectiles at high velocity into plant cells. It had been widely used for the production of transgenic plants that are not susceptible to *Agrobacterium*. However, use of particle gun transformation is decreasing as monocot plants, such as cereals, grasses, and *Alliums* that were once regarded as not susceptible to *Agrobacterium* have now been transformed by *Agrobacterium*.

Given the excellent rates of shoot regeneration obtained from some vegetable Brassica explants and the problems with *Agrobacterium*-mediated transformation, it is surprising that particle gun transformation has not been used for the production of transgenic vegetable Brassicas. Puddephat *et al.* (1999) have demonstrated transient GUS expression in broccoli cotyledon discs by particle gun transformation. They made a detailed study of the factors that influence several particle gun delivery parameters. However, they only studied transient expression 24 hours after bombardment and did not produce stable transformants. Subsequently, Nugent *et al.* (2006) have also attempted particle gun transformation of cauliflower explants but with no transgenic shoots obtained.

2.1.4 Floral dipping

In *Arabidopsis thaliana*, several simple *in planta* nontissue culture transformation methods have been developed including seed imbibition and floral dipping (reviewed by Bent, 2000). The floral dip method is now widely used for *A. thaliana* transformation and involves dipping flowering plants briefly in a solution of *Agrobacterium* and surfactant and, subsequently, harvesting and screening seed for transgenic progeny. The advantage of this method is that it is simple and convenient with no tissue culture system required, thus decreasing costs and labor input. In addition, possible somaclonal variation from the regeneration process can be avoided. This method

may be applicable to other Brassicaceae that are recalcitrant to regeneration from tissue culture. However, in *A. thaliana* thousands of seeds are easily obtained from one plant and though the overall transformation rates are low, 10–15 transformants may be recovered per plant. Qing *et al.* (2000) adopted this method for transformation of Pak choi and obtained Basta-resistant plants. Whole plants were immersed in *Agrobacterium* under vacuum. Selfed seed were collected and sprayed with Basta. Two Basta-resistant seedlings out of approximately 20 000 were obtained and molecular and progeny analysis confirmed gene insertion and transmission to progeny. While the transformation rate was extremely low, this study demonstrates one of only a few reports of the successful production of transgenic Pak choi. Yu *et al.* (2004) unsuccessfully attempted floral dipping for production of Chinese cabbage but were able to obtain transformants by pollen tube transformation. More recently, Zhandong *et al.* (2007) successfully obtained 43 transgenic Chinese cabbage plants from 1831 seeds (2.35%) using *A. tumefaciens* mediated floral dipping.

2.1.5 Plastid transformation

Plastid transformation offers several advantages over nuclear transformation including the potential for high levels of protein production, the potential for transgene containment in species with maternal inheritance of plastid DNA, absence of gene silencing, and the ability to express multiple genes. Introduced traits include herbicide, insect and disease resistance, abiotic stress tolerances, and vaccines. Plastid transformants have been produced in a number of plants including potato, tomato, carrot, soybean, cotton, petunia, *Arabidopsis*, and *Brassica napus* (reviewed in Maliga, 2004). However, in vegetable Brassicas only a single plastid transformant has been obtained to date in cauliflower using PEG-mediated DNA uptake into mesophyll protoplasts (Nugent *et al.*, 2006).

2.1.6 Selection of transformed tissue

Kanamycin has been widely used as a selection agent for the production of vegetable Brassicas

(see Table 1). However, hygromycin and herbicide resistance have also been used in addition to visual markers such as GUS and green fluorescent protein (GFP) (see Table 1). Cao *et al.* (1999) and Lee *et al.* (2004) found hygromycin to be a more effective selection agent than kanamycin. Zhandong *et al.* (2007) used marker-free selection by selecting transgenic plants on the basis of the trait of interest, i.e., virus resistance.

2.2 Enhancing Transformation Rates

Transgenic plants have been obtained from most vegetable Brassicas, but transformation rates are low. In an effort to increase transformation rates many factors have been studied concentrating on cultural conditions, i.e., both explant and bacterium, and also genetic factors.

2.2.1 Culture conditions

The frequency of production of transgenic vegetable Brassica plants varies widely between species and cultivar. Due to the low efficiency of transformation, several authors have used transient GUS expression as a simple assay for establishing the optimal conditions for transformation. They have found several factors influence transformation efficiency including explant age, duration of co-cultivation with *Agrobacterium*, strain, cultivar, use of feeder cells, acetosyringone, and micropore tape. The GFP reporter gene has also been used to monitor transformation and has the advantage that transformation can be monitored *in situ* nondestructively as shown by Cogan *et al.* (2001) with broccoli.

The explant source, most commonly used for *Agrobacterium* co-cultivation, includes seedling-derived cotyledonary petioles and hypocotyls with a few reports using peduncles or petioles (reviewed in Christey and Braun, 2004). Seedling age is important as Chen *et al.* (2001) reported that hypocotyl and cotyledon explants from 3-days-old broccoli seedlings gave higher putative transformation frequencies than 9-days-old seedlings. Bhalla and Smith (1998a) also found seedling age was important as explants from 4-days-old cauliflower seedlings gave higher rates of transformation than 7–14-days-old seedlings. Chen *et al.* (2001)

compared transformation of broccoli cotyledon, hypocotyl, and peduncle explants using both co-culture and vacuum infiltration for *Agrobacterium*-mediated transformation. However, vacuum infiltration adversely affected regeneration from cotyledon and hypocotyl explants. Regeneration rates on kanamycin selection were slightly higher for peduncle explants after vacuum infiltration (23%) compared with direct soaking (17%). The overall putative transformation rates varied from 0.6% to 14.7% depending on explant source and cultural conditions.

Tsukazaki *et al.* (2002) used transient GUS expression to determine the best conditions for *Agrobacterium*-mediated transformation of cabbage doubled haploid (DH) lines. The best conditions were hypocotyl explants precultured on medium containing 50 μ M acetosyringone for 3 days, followed by co-cultivation with strain LBA4404 for 3 days. Under these conditions, the stable transformation efficiency was 3%.

Manipulation of co-cultivation conditions can also increase transformation rates. Henzi *et al.* (2000a) improved the rate of HR production from leaf explants of Shogun broccoli from 8% to 33% by the use of acetosyringone in the bacterial culture medium, addition of a *B. campestris* feeder layer and use of acetosyringone and mannopine in the co-cultivation medium.

Bhalla and Smith (1998a) found that several factors were important in the successful production of transgenic cauliflower plants including explant age, co-cultivation time, and delayed introduction of selection. Shoots could not be regenerated from cauliflower explants when selection was applied immediately after *Agrobacterium* inoculation. A 1-week delay in selection resulted in the recovery of transgenic plants. Chen *et al.* (2001) found a 7–10-day recovery was needed with broccoli peduncle explants before kanamycin selection was used.

In a detailed study with cauliflower, Chakrabarty *et al.* (2002) used transient GUS expression to evaluate the optimum conditions for *Agrobacterium*-mediated transformation of hypocotyl explants. Explant age, preculture period, bacterial strain, and density were found to be critical factors in the transformation efficiency. The use of the *Agrobacterium* strain GV2260 considerably improved expression rates compared with LAB4404, A208, or EHA105. They also noted that a 7–10-day delay was required to enable

the production of transgenic cauliflower. Optimal conditions for transformation of hypocotyl explants were 2 days of preculture, 2 days of co-cultivation with a 7–10-day delay prior to transfer to 20 mg l⁻¹ kanamycin.

Jin *et al.* (2000) were unsuccessful in applying the seedling explant method developed by Metz *et al.* (1995) for cabbage to their cabbage lines. However, they successfully produced *Bacillus thuringiensis* (Bt)-resistant cabbage with a modified protocol after testing several factors that affect the virulence of *Agrobacterium* and regeneration of transgenic cells. They found that the wounded ends of explants incurred severe necrosis from *Agrobacterium* infection, and the amount of kanamycin used for selection was too high. These problems are commonly reported not only in cabbage but have been also noted in cauliflower and broccoli (M.C. Christey, unpublished observations). Jin *et al.* (2000) found that reducing the *Agrobacterium* concentration used for infection, excluding tobacco cells from culture, increasing the agar concentration to 1%, and decreasing the level of kanamycin used for selection enabled the production of transgenic cabbage plants.

2.2.2 Genetic factors

In vegetable Brassicas, there are clear effects of species and cultivar on *A. tumefaciens*- and *A. rhizogenes*-mediated transformation rates. Sparrow *et al.* (2004b, c, 2007) investigated the genetic basis of two key variables of *A. tumefaciens*-mediated transformation in broccoli. They showed genetic control of shoot regeneration and susceptibility to *Agrobacterium* is controlled by additive and dominant gene effects. They mapped quantitative trait loci (QTL) associated with *Agrobacterium* susceptibility. They demonstrated the ability to introduce or increase shoot regeneration potential and susceptibility to *Agrobacterium* into otherwise recalcitrant lines. Their studies resulted in the identification and use of phenotype markers to select potential candidates for successful transformation. Sparrow *et al.* (2004a) have selected a rapid cycling (RC) *B. oleracea* line, DH1012, for high regeneration and transformation ability. The use of this RC DH1012 line by Christey *et al.* (2006a) enabled the production of large numbers of fertile transgenic

plants quickly. Plants were flowering three months after transfer to the greenhouse. The use of DH1012 enabled the rapid production and analysis of transgenic plants to ensure that the gene constructs were functional (Christey *et al.*, 2006a). The use of this line has been particularly invaluable in our other research where it is important to analyze large numbers of transgenic plants to ensure that the phenotypic changes noted are actually due to the inserted gene and not an effect of somaclonal variation. In addition, the rapid generation of progeny enables progeny analysis to be conducted.

Cogan *et al.* (2001) studied the production of HRs transgenic for GFP production from eight *B. oleracea* cultivars including broccoli, cabbage, cauliflower, and kale. Significant differences in transformation rates were noted between broccoli cultivars ranging from 1% to 58%. Three of the broccoli cultivars were then subjected to anther culture and the transformation rates of the DH lines studied. These lines showed considerable variation for transgenic root production with two populations including lines showing significantly increased transformation rates compared to the parental cultivar. Anther culture derived DH lines of the cabbage cultivar Hawke also showed considerable variation for transgenic root production ranging from 6% to 85%.

Cogan *et al.* (2002, 2004) studied GFP expression after *A. rhizogenes*-mediated transformation on 73 lines of a Chinese kale \times broccoli DH mapping population. They identified genotypes that showed an increase in transformation efficiency from 14% and 20% (parental lines) to over 83%. They identified three QTLs for transgenic root production, two of these were the same as those associated with adventitious root production. They identified lines with high rates of transgenic root production that may be useful in the development of high-throughput transformation systems. The identification of QTL regions in these studies associated with control of *Agrobacterium*-mediated transformation will assist in the identification of the most amenable genotypes and aid in the development of genotype-independent transformation systems. In addition, marker-assisted selection may be used to transfer these alleles to recalcitrant genotypes, enabling the transformation of previously nonamenable genotypes.

2.2.3 Other factors to consider

In addition to the choice of cultivar, *Agrobacterium* strain, selectable marker and other culture conditions, choice of promoter needs to be also considered. The cauliflower mosaic virus (CaMV) 35S promoter is widely used in the production of transgenic plants. However, Al-Kaff *et al.* (2000) have noted that infection of plants with CaMV leads to silencing of genes controlled by the 35S promoter. They analyzed the response to CaMV infection of a transgenic oilseed rape line containing the phosphinothricin acetyltransferase (*bar*) gene regulated by the 35S promoter. CaMV infection altered the expression of the herbicide tolerance gene such that plants became susceptible to the herbicide. Susceptibility to the herbicide was most likely a result of transcriptional gene silencing of the transgene. This is important as it means that CaMV infection of a crop could have a major impact on transgenic expression in a cruciferous crop and destabilize a commercially important trait.

2.3 Agronomic Traits Introduced

2.3.1 Insect resistance

Insect-resistant crops expressing *Bacillus thuringiensis* toxin (*cry*) genes from *Bt* were first grown commercially in 1996, and since then the acreage of *Bt*-transgenic crops has increased dramatically with over 25 Mha planted worldwide in 2005, mainly in maize and cotton (James, 2005). Various *cry* genes from *Bt* have been introduced into vegetable Brassicas including broccoli, cabbage, cauliflower, collards, and swede (Table 1) and been shown to successfully control important insect pests such as diamondback moth (*Plutella xylostella*) and cabbage white butterfly (*Pieris rapae*).

In addition to *cry* genes, the cowpea trypsin inhibitor has also been shown to confer insect resistance (Table 1). Trypsin inhibitors are a type of protease inhibitor that is capable of controlling a wide spectrum of insect pests. Ding *et al.* (1998) produced insect-resistant transgenic cauliflower expressing a sweet potato trypsin inhibitor gene. Transgenic cauliflower plants were obtained with a high degree of protection against

the Brassica Lepidopteran pests *Spodoptera litura* (cut worm) and *Plutella xylostella* (diamondback moth).

As with all traits, the use of genes used in *B. napus* is likely to be of value for use in transformation of vegetable Brassicas as often the same insects and disease are a problem. There are no reports in vegetable Brassicas of the introduction of lectin genes for insect control. However, in *B. napus* good control of the pollen beetle (*Meligethes aeneus*) has been achieved in plants transformed with a construct containing the pea lectin gene under the control of a pollen specific promoter (Ahman *et al.*, 2006).

2.3.2 Disease resistance

Important fungal, bacterial, and viral diseases affecting vegetable Brassicas include black rot, soft rot, downy mildew, clubroot, *Alternaria* blight, and CaMV. Protoplast fusion has been investigated as a means to introgress pest and disease resistance from other Brassicaceae species (Christey, 2004) but transformation technology offers an alternative approach.

2.3.2.1 Bacterial

Braun *et al.* (2000) introduced antibacterial genes from nonplant sources into cauliflower in an attempt to produce black rot-resistant cauliflower. They introduced the Shiva protein, which is a synthetic analogue of cecropin B from the giant silkworm moth, and the magainin II peptide derived from the African clawed frog. *In vitro* bacterial assays using crude leaf extracts confirmed increased resistance to black rot but greenhouse screening failed to show any increased resistance compared to controls. Zhao *et al.* (2006) have also introduced Shiva and cecropin B into Chinese cabbage but while transgenic plants were obtained and gene expression confirmed by Northern analysis, no bacterial assays were conducted.

Glucose oxidase catalyzes the oxidation of glucose generating H_2O_2 as a by-product. H_2O_2 effectively inhibits bacterial and fungal growth and plants transgenic for glucose oxidase show enhanced disease resistance. However, some deleterious phytotoxic effects of glucose oxidase

have been noted in transgenic plants. Cabbage expressing a glucose oxidase gene from *Aspergillus niger* showed enhanced disease resistance to black rot caused by *Xanthomonas campestris* but also showed phytotoxic effects (Lee *et al.*, 2002). Plants showed significant growth retardation, and seed set was dramatically reduced, with only a few seed produced.

2.3.2.2 Fungal

Chitin is an important component of fungal cell walls. Chitinase genes cloned from plants and fungi have been transferred into a number of plant species and resistance to a broad range of fungal pathogens obtained. Mora and Earle (2001) produced transgenic broccoli plants expressing an endochitinase gene from the biocontrol fungus *Trichoderma harzianum*. Transgenic plants were obtained with 14–37 times higher endochitinase levels than controls. Transgenic plants inoculated with *Alternaria brassicicola* showed significantly less severe disease symptoms than controls. Interestingly, polyploid plants were highly susceptible regardless of their endochitinase activity. In contrast, lesion size of plants inoculated with *Sclerotinia sclerotiorum* was not statistically different from controls.

2.3.2.3 Viral

Passelègue and Kerlan (1996) transformed cauliflower with two CaMV-derived genes in an attempt to produce CaMV-resistant cauliflower. They used the capsid gene and the antisense gene VI of CaMV. While reverse transcriptase-polymerase chain reaction demonstrated the presence of CaMV gene transcripts in all plants, the amount of RNA transcribed was very low, in contrast to the hygromycin resistance (*hpt*) gene transcript. In plants transformed with the capsid gene, the capsid protein could not be detected. The response to CaMV infection was not tested. In contrast, Zhandong *et al.* (2007) successfully obtained high levels of resistance to turnip mosaic virus (TuMV) in Chinese cabbage plants transformed with the antisense *TuMV* replicase (*NIb*) gene. Plants were transformed

using marker-free *A. tumefaciens* mediated floral dipping.

2.3.3 Herbicide resistance

The incorporation of herbicide resistance into vegetable Brassicas would enable growers to more efficiently control weeds. Basta resistant broccoli has been produced and field tested by Christey *et al.* (1997) and Waterer *et al.* (2000). Waterer *et al.* (2000) field tested six transgenic lines and noted that herbicide application had little effect on head quality and marketable yield of most lines. Christey *et al.* (1997) field tested four transgenic lines and also noted phenotype was normal though plants were not sprayed in the field. Greenhouse application of Basta to seedlings demonstrated they were resistant.

2.3.4 Flowering control

Hybrid seed production is an important breeding goal in vegetable Brassicas as hybrid seed offers many benefits including increased vigor and greater uniformity. The introduction of male sterility into vegetable Brassicas would aid production of hybrid seed. Transformation approaches have been used in cabbage, cauliflower, and Chinese cabbage to induce male sterility (Table 1). In cauliflower, Bhalla and Smith (1998a) introduced an antisense pollen-specific gene linked to a pollen-specific promoter into cauliflower and obtained the expected sterility of 50% of pollen. In Chinese cabbage, introduction of an antisense version of the *CYP86MF* gene linked to a tapetum-specific promoter induced male sterility (Yu *et al.*, 2004). Lee *et al.* (2003) also used a tapetum-specific promoter to induce male sterility in cabbage through the introduction of the cytotoxic diphtheria toxin A chain.

Self-incompatibility prevents self-fertilization and promotes outcrossing. In vegetable Brassicas self-incompatibility is used for hybrid seed production but has a number of drawbacks, including breakdown of incompatibility, labor intensiveness, and genetic complexity of the system. In Brassicas self-incompatibility is sporophytically controlled by multiallelic genes at the *S*-locus. Two genes

have been identified at the *S*-locus, *S*-locus glycoprotein (*SLG*) and *S*-locus receptor kinase (*SRK*). *SLG* encodes a secreted glycoprotein in the wall of the stigma papillary cells and *SRK* encodes a transmembrane receptor kinase. A self-incompatible response occurs when the same *S*-allele is expressed in pollen and stigma. Toriyama *et al.* (1991) introduced an *SLG* gene from *B. campestris* S8 homozygote and were able to alter the self-incompatibility phenotype of pollen and stigma. The self-incompatible Chinese kale and partial compatible broccoli plants were fully compatible upon self-fertilization.

2.3.5 Postharvest attributes

Broccoli is harvested when the flowering head is immature and growing rapidly. Postharvest senescence is rapid with loss of chlorophyll resulting in yellowing of the head. Ethylene plays an important role in the yellowing of broccoli as chlorophyll loss is associated with an increase in floret ethylene synthesis and chlorophyll loss can be delayed through the use of inhibitors of ethylene action and biosynthesis. Several groups are conducting transgenic research aimed at increasing the shelf life of the ethylene-sensitive broccoli. Antisense versions of two key regulatory genes in the ethylene biosynthesis pathway, i.e., ACC oxidase and ACC synthase have been used to produce transgenic broccoli plants with reduced ethylene synthesis. However, the reduction in ethylene production has only resulted in increases in shelf life of 1–2 days.

In order to delay postharvest senescence in broccoli, Henzi *et al.* (1999a, b) used *A. rhizogenes*-mediated transformation to express an antisense ACC oxidase gene from tomato into broccoli. Plants showed reduced ethylene production but little effect on postharvest senescence (Henzi *et al.*, 2000b). Gapper *et al.* (2002) used *A. tumefaciens*-mediated transformation to introduce an antisense ACC oxidase gene from broccoli into broccoli. This gene was driven by the asparagine synthetase promoter from asparagus that is expressed at harvest as shown by fusion of this promoter to the GUS gene and analysis of expression patterns (Kenel, 1999). Several lines were obtained with reduced ethylene production

and delayed postharvest senescence (Gapper *et al.*, 2002). Higgins *et al.* (2006) have also shown that broccoli transgenic for antisense versions of ACC synthase and ACC oxidase have reduced ethylene production, which correlates with delayed chlorophyll loss.

Cytokinin has also been shown to be involved with broccoli senescence as application of cytokinin to broccoli heads can delay postharvest yellowing. Gapper *et al.* (2002) reported the introduction of an isopentenyl phosphotransferase (*IPT*) gene into broccoli but results on the effect of postharvest senescence were not reported. Some plants had an abnormal phenotype typical of constitutive *IPT* expression. Chen *et al.* (2001) also introduced an *IPT* gene into broccoli under the control of senescence-associated promoters and demonstrated retardation in postharvest yellowing in broccoli heads and leaves. They reported that 31% of transformants exhibited delayed yellowing in detached leaves, 16% in floret branchlets, and 7% in both leaves and floret branchlets.

Eason *et al.* (2005) and Chen *et al.* (2004a) have also delayed senescence in broccoli through transformation with either an antisense cysteine protease or mutant ethylene response sensor gene. In both cases, senescence was only delayed by 1–2 days.

As there are several other genes whose expression is increased at broccoli harvest, it is likely that down-regulation of these genes through antisense or RNA interference will also lead to the production of broccoli with delayed senescence. It is likely that future research will involve the introduction of these genes into green leafy vegetables such as Chinese cabbage and Pak choi that also show postharvest deterioration due to ethylene.

2.3.6 Altered stress tolerance

Due to concerns regarding the increasing demand for water and the need to produce plants with increased tolerance to salt stress, transgenic plants are being produced with drought tolerance and salt stress particularly in rice and maize. Similar research is also being conducted with vegetable Brassicas. For example, Bhattacharya *et al.* (2004) have produced cabbage plants with

enhanced salt tolerance through the introduction of the bacterial glycinebetaine biosynthesis (*BetA*) gene for biosynthesis of glycinebetaine. Detailed analysis of three independent transgenic lines showed improved growth and development under salt stress compared with the control. Park *et al.* (2005) produced Chinese cabbage transgenic for the *B. napus* late embryogenesis abundant (*LEA*) gene and obtained plants with enhanced drought tolerance and salt tolerance.

2.3.7 Altered health benefits

2.3.7.1 Anthocyanins

Flavonoids, such as anthocyanins, are known as antioxidants *in vitro*. Their presence in many fruits and vegetables has prompted researchers to validate epidemiological links between a diet rich in fruit and vegetables and the reduced risk of many diseases related to aging. However, some vegetable Brassicas, such as cauliflower, are low in anthocyanins. In an attempt to manipulate pigment biosynthesis to increase the health benefits of vegetables, the effect of a regulatory locus of flavonoid content was assessed. *Agrobacterium tumefaciens*-mediated transformation of a *Brassica oleracea* line, selected for high transformation ability by Sparrow *et al.* (2004a), was used to produce plants transgenic for the maize *lc* (leaf color) locus. *Lc* is a regulatory gene in the anthocyanin pathway and it is expected that its presence will increase the flavonoid content. Seedling explants were co-cultivated with *Agrobacterium tumefaciens* strain LBA4404 containing a binary vector with a neomycin phosphotransferase II (*NPTII*) gene. Under tissue culture conditions *lc*-containing plants were green with no visible increase in anthocyanin production. However, on transfer to greenhouse conditions the higher light resulted in visible signs of pigmentation within 1 week. Increased pigmentation was apparent in stems, petioles, main leaf veins, and sepals. *Lc*-containing lines had 10–20 times higher levels of total anthocyanins compared with controls. In addition, antioxidant activity of *lc*-containing lines was 1.5 times higher than controls (Braun *et al.*, 2006).

2.3.7.2 Sulfur

Sulfur metabolites impart key nutritional and sensory attributes to *Allium* and crucifer crops. S-methyl cysteine sulfoxide (MCSO) occurs in all *Allium* and *Brassica* spp. and is associated with “cabbage” flavors, human health benefits but also kale anemia of ruminants. To investigate biochemical and molecular aspects of plant sulfur metabolism the effect of down-regulating genes involved in thiol precursor biosynthesis and MCSO production was investigated with an RNA interference vector constructed for the enzyme γ -glutamyl cysteine synthetase (GGCS).

Agrobacterium tumefaciens-mediated transformation of a rapid-cycling *Brassica oleracea* line selected for high transformation ability was used to produce transgenic plants. Seedling explants were co-cultivated with *A. tumefaciens* strain LBA4404 containing a binary vector with an *NPTII* gene for selection of transgenic plants. Preliminary results on MCSO levels using high-performance liquid chromatography (HPLC) analysis has shown a wide range of results with some lines showing a large decrease in MCSO levels (Christey *et al.*, 2006b). Over 25 independent T₀ transgenic lines have now been screened for MCSO or precursor compounds using HPLC. A range of results have been obtained with some lines showing a large decrease in MCSO levels. T₁ seed from selected lines segregating for the construct has been collected. Analysis on T₁ seed for a range of metabolites upstream and downstream of GGCS in the sulfur assimilation pathway have been conducted to determine if knockdown of this gene affects sulfur flux. In three transgenic lines there was a glutathione decrease with no apparent effect on growth under normal nutrient conditions, while levels of γ -glutamyl cysteine and cysteine appeared relatively stable. The relationship between this glutathione decrease and MCSOs will be determined in future work.

2.3.7.3 Vitamins and amino acids

Current advances in genetic engineering have enabled the production of plants with alterations in a range of vitamins or amino acids for either improved human or animal nutrition. For

example, Lu *et al.* (2006) have produced transgenic cauliflower with β -carotene accumulation and Wahlroos *et al.* (2004) have produced oilseed *B. rapa* with increased histidine content. It is likely in the future further transgenic vegetable Brassicas with altered vitamin or amino acid content will also be developed.

2.4 Field Testing

The first field trial of transgenic plants was conducted in 1986 with the first commercial release of a transgenic crop in 1994. Since then there has been a rapid expansion in the commercial release of transgenic crops. However, while oilseed forms of *B. napus* and *B. campestris* are no longer regulated in the United States and transgenic canola is widely grown (Christey and Woodfield, 2001), there are only rare reports of vegetable Brassica field trials and there are no nonregulated or commercial use of vegetable Brassica products. Both *A. tumefaciens*- and *A. rhizogenes*-derived plants have been field tested. *A. tumefaciens*-derived Basta resistant broccoli was field tested by Waterer *et al.* (2000) and Christey *et al.* (1997). The Collaboration on Insect Management for Brassicas in Asia and Africa (CIMBAA) aims to bring to Asia (initially India) and Africa a safe and sustainable control strategy for controlling damaging insect pests of cabbages and cauliflowers. *Bt*-containing vegetable Brassicas (cabbage and cauliflower) are being developed and field trials are planned. In New Zealand, *A. rhizogenes*-derived vegetable Brassicas have been field tested by Christey *et al.* (1999). In addition, a field test of a range of *Bt*-containing vegetable Brassicas is in progress in New Zealand (Christey, 2006).

2.5 Environmental Concerns with GM Vegetable Brassica Plants

The field testing and potential commercial release of transgenic vegetable Brassicas has raised concerns about the environmental impact of these crops. In particular, concerns relate to the possible movement of transgenes through pollen transfer from vegetable Brassicas to weedy relatives. However, seed certification schemes

contain internationally recognized guidelines for sowing distances to minimize seed contamination by pollen transfer. If these guidelines and strict management conditions are followed then pollen transfer will be less of a problem (reviewed in Christey and Woodfield, 2001). In addition, genetic strategies are available to prevent pollen transfer. Use of male sterile lines would prevent pollen transfer. Chloroplast transformation has recently been reported in vegetable Brassicas by Nugent *et al.* (2006) and its adoption could alleviate some of the environmental concerns associated with pollen due to maternal inheritance of the cytoplasm in Brassicas. Another method to decrease concerns or to provide more targeted gene expression is the use of tissue or developmental specific promoters. For example, Baranski *et al.* (2004) determined the expression patterns of four tissue-specific promoters fused to GUS for their expression in cauliflower tissues in comparison with the constitutive 35S promoter. This research identified promoters with low expression in curds.

Other concerns relate to nontarget impacts on beneficial organisms and the soil biota. Current field trials of vegetable Brassicas in New Zealand are ensuring these concerns are addressed by undertaking extensive nontarget impacts research on nontarget beneficial organisms (Christey, 2006).

Biosafety concerns are also raised due to the presence of marker genes in the GM plants. A potential advantage of *A. rhizogenes* is its use for the production of marker-free transgenic plants. High rates of co-transformation of Ri and T-DNA occur and therefore the hairy root phenotype can be used to select transgenic roots. The genes may be integrated into different chromosomes and therefore independent segregation in the next generation will produce transgenic plants without the marker gene. This has been demonstrated in cauliflower by Christey *et al.* (1999) and in broccoli by Higgins *et al.* (2006). In addition, the use of the *GFP* gene as a marker gene will overcome concerns raised by the use of antibiotic marker genes. Recently, Zhandong *et al.* (2007) successfully demonstrated the production of transgenic Chinese cabbage plants transformed using marker-free *A. tumefaciens*-mediated floral dipping. Seeds produced after floral dipping were screened for the trait of interest, i.e., virus resistance. However, polymerase chain reaction

analysis was required to confirm gene presence as a large number of TuMV-resistant plants, identified by TuMV inoculation, did not contain the transgene.

3. FUTURE PRODUCTS

Transformation systems have been developed for several vegetable *B. oleracea* and *B. rapa* types, but transformation remains difficult with rates low and genotype dependent. A range of genes of agronomic importance have been introduced including pest and disease resistance. Research is already being conducted to produce plants with altered adaptation to water and salt stress. It is likely that a range of products with altered health benefits are likely to be the next generation of transgenic vegetable Brassicas. While no transgenic vegetable Brassicas have yet been released commercially, this is likely to occur soon if environmental and public concerns are adequately addressed.

Radish

Ian S. Curtis

AgriLife Research Center, Weslaco, TX, USA

1. INTRODUCTION

1.1 History, Origin, and Distribution

Radishes are grown in all continents of the world. One of the first indications on the cultivation of radish were the inscriptions on walls of the Pyramids dating 2000 BC, but Herodotus (c. 484–424 BC) believed radish was a major crop in Egypt some 5000 years ago (Becker, 1962). During such ancient times, it is believed that radishes were cultivated as an oilseed crop. Over 2000 years ago, the cultivation of radishes spread to eastern China, where the crop was domesticated into producing a wide diversity of roots. By the time of Christianity, the cultivation of several forms and colors of radish had been described in Roman writings. However, the introduction of radishes to the New World was not until Columbus discovered the Americas. Indeed, at that time, only the large, late-winter types were grown but by the turn of the 16th century the short-season radishes were introduced.

Radishes are generally categorized into two groups based on the size of their edible swollen hypocotyl and tap root. The small-rooted, short-season (or 1-month) radishes are commonly cultivated in the temperate regions of Europe, the United States (especially coastal regions of California and Florida), and also in Arctic regions under protection. Large-rooted (or 3-month) radishes are mainly grown in Asia but are suited to both temperate and tropical conditions.

There are two other forms of radish that fail to produce an edible root. Fodder radish, is grown in Southeast Asia and Europe as leaf fodder for animal feed and also as a green manure. Mougridish or rat-tail, is grown for its leaves and long immature seed pods (80 cm length) in Southeast Asia.

The small-rooted radishes are grown for salads and consumed as a raw vegetable. These roots can vary in shape (elongated to flattened spheres) and in skin color (white or red; Figures 1a and b). This vegetable is popular in gardens as an intercrop between slower growing crops and also with specialist growers in market gardens.

The large roots are more diverse than the European types especially in terms of their skin color (green, yellow, purple, and black) and flesh color (white, red, purple, or green; Figure 1c). Remarkably, the large, spherical Asian varieties grown in China and Japan can weigh up to 40 kg. In Tibet and Northeast China, where food is in short supply during winter months, the roots are stored in the ground. In Korea, the roots are commonly pickled with other vegetables in large pots underground and sometimes consumed as *kimchi*, which is the country's national dish. This radish is also culturally extremely important in Japan, with the building of temples at sites, where radish has been cultivated for centuries (e.g., Asakusa), and restaurants specializing in an array of dishes using both root and leaves for the making of bread, soup, jelly, and ice cream!

1.2 Botanical Description

For many years the taxonomy of radishes has been based on inadequate knowledge of the variation within the species. To date, the most reliable classification scheme combines the main cultivar form *Raphanus sativus* with its wild relatives *R. raphanistrum*, *R. landra*, and *R. maritimus* (Pistrick, 1987). These taxa have $2n = 2x = 18$ chromosomes and cross to form fertile hybrids (Lewis-Jones *et al.*, 1982). As these wild taxa occur as agricultural weeds, gene flow between cultivated and wild species seems inevitable. The cultivated forms of radish can be divided into three groups:

- Convar. *oleifera* – oilseed and fodder radishes
- Convar. *caudatus* – rattail radish (or var. *mougri*)
- Convar. *sativus* – all edible root forms, which can be further divided into geographic types, in-

cluding European, Chinese (including Japanese types as they are derived from the same ancestor), and Indian.

At present there is no division between small-rooted (also referred to as var. *radicula*) and long-rooted types (var. *nigra*, *niger*, *sinensis*, *acanthiformis*, or *longipinnatus*) but the phenotypic differences between the two groups appear to be a result of commercial development.

During the early part of the 20th century, crosses were made between *R. sativus* and *Brassica oleracea* ($2n = 18$), *B. rapa* ($2n = 20$), and *Sinapis arvensis* ($2n = 18$) to understand the affinities between their genomes (Karpechenko, 1927). The *Raphanus*–*B. oleracea* hybrids, including fertile allopolyploids, revealed that both genomes were similar. However, in the wild, there is no evidence for such hybrids to exist.

Radish belongs to the family Brassicaceae and exists as an annual and biennial. The 1-month radishes are annuals and are cultivated mainly in spring and summer; the large-rooted radishes are harvested later in the year and are classified as both annual and biennial. The DNA amount in the unreplicated haploid nuclear genome, or 1C value (Swift, 1950) of *R. sativus* L. is 0.5 pg (picogram) (Bennett and Leitch, 1997). In comparison, the radish genome is more than double the size of *Arabidopsis thaliana* (L.) Heynh. (0.2 pg) but less than half the size of the allotetraploid *Brassica napus* (1.4 pg).

During early stages of growth the radish forms a rosette of leaves attached by a short stem. The short-season radishes develop a shorter top growth (20–30 cm height) and the root swells within 2–3 weeks, larger rooted radishes produce an extensive rosette (90–120 cm), and some cultivars can form edible roots more than 150 cm in length.

A cold period (4–6 °C) for approximately 7 days under long-day conditions (16-h daylength) can cause the bolting of biennials. The annuals form bolts once the root reaches edible size, especially when the plants are exposed to warm day temperatures (above 18 °C). The bolting of a radish plant results in the nutrients from the root being transferred into the developing stem resulting in a radish unfit for the market.

In the open field, radishes are not aggressive competitors. The crop can tolerate most well-drained soils, which are free from excessive debris

and stones. Radishes are very hardy, in that, they can be sown before the end of frosty weather. However, the large-rooted Korean ecotypes will form bolts when exposed to 4–6°C for 7 days. The 1-month-old radishes are grown in rows 20 cm apart and 2 cm between plants; large-rooted types require greater spacing. Uniform soil moisture is critical for the formation of healthy roots. Periods of drought can cause surface cracking of the enlarged root and the flesh to become tough and fibrous. The number of crops per year depends on the length of the growing season. As a guide, the market gardens in the United Kingdom can produce more than four crops of the small-rooted radishes per year and those in Asakusa (Japan) can produce 2–3 crops of the long-rooted radishes.

1.3 Economic Importance

Although radishes are grown globally, in the Far East, its cultivation is far more widespread. Japan alone produces 30 times more radishes by weight compared to the whole of Europe (Crisp, 1995). Recent governmental figures for Korea and Japan revealed that radish cultivation is ranked fifth and fourth, respectively, in terms of its popularity as a vegetable crop (Table 1). In China, the large-rooted radishes are grown in over 1.2 million ha of arable land (Curtis, 2004) making radish the most widely grown root crop in the Far East.

Table 1 Ten most popular crops grown in Korea and Japan (area = 1000 × ha, yield = 1000 t)

Despite the popularity of radish cultivation worldwide, the crop has been regarded as adding little to nutrition (Pearce, 1987). However, studies in the 1950s reported that radish is an excellent source of vitamins B and C and a good source of calcium (Quisumbing, 1951). To understand the nutritional composition of radish roots, a recent study was performed on the large-rooted types of radish (R. Yang, personal communication). This study performed at the Asian Vegetable Research and Development Center (AVRDC) in Taiwan confirmed that the root is an important source of nutrients (Table 2).

Since the 1920s, the radish has been used for medicinal purposes in India. The seeds were used as an emmenagogue for the treatment of gonorrhoea and the root was found to be useful for treating haemorrhoids, syphilis, and bladder problems (Nadkarni, 1927). At that time, there was no indication which chemicals in the plant were involved in treating such medical problems. In a recent review, two chemicals have been identified in radish that could have potential as being important medicinally (Curtis, 2007).

In summary, peroxidase is present in rich amounts in the roots of radish and acts as an

oxidoreductase enabling it to scavenge dangerous-free radicals. Such an enzyme could be useful in reducing the occurrence of coronary heart diseases and atherosclerosis. To determine the value of peroxidase on reducing excess fat in the blood, a clinical trial was conducted using hyperlipidemic mice fed with different purities of peroxide from radish and horseradish (Wang *et al.*, 2002). Their results revealed that the levels of total serum cholesterol, triglyceride, blood glucose, and lipid peroxidation in the small intestine and liver were significantly reduced compared to mice not fed with peroxidase. This preliminary trial suggests that peroxidase from radish may help in reducing the chance of hyperlipidemia in mice, but such trials are necessary on people to be able to truly evaluate its value to human medicine.

The wounding of crucifers can result in a large production of organic isothiocyanates. These highly reactive chemicals are valuable to the medical world as they have antimicrobial, antimutagenic, and anticarcinogenic properties. A study was made to see whether the main isothiocyanate in radish, 4-(methylthio)-3-butenyl isothiocyanate (MTBITC) had a positive effect as an antimutagen on UV-induced *Escherichia coli* b/r WP2 (Nakamura *et al.*, 2001). Although there were varietal differences in the amount of MTBITC being produced from wounded roots, this bacterial mutagenic assay revealed a positive response as an antimutagen. If such a response can be repeated in human cells, then a medically important chemical would have been identified in radish.

1.4 Traditional Breeding

For many centuries, radish breeding has been achieved by mass selection or combined mass pedigree selection. The radish plant has a sporophytic incompatibility system, where the papillae on the stigma surface forms an elusive barrier to pollen tube penetration. Breeders have overcome this problem by disrupting the stigma surface or by applying pollen to the conducting tissue of the style to allow normal seed set after selfing. However, more recently, breeders have adapted the bud pollination procedure to produce seed (Roggen and Van Dijk, 1973).

The 1960s saw the production of hybrid seed utilizing the incompatibility system and the Ogura (Ogura, 1968) cytoplasmic male-sterility (CMS) in Japan. Although the production of F₁ hybrid seed is expensive, the higher economic value of the large-rooted Asian radishes made such a product counter productive. Japanese seed companies exploited the incompatibility system in radish for the marketing of the F₁ long white “mouli” type to western growers. Recent molecular studies have revealed that the Ogura CMS is under the control of *orf138* (Bonhomme *et al.*, 1992) from the wild relative *R. raphanistrum* (Yamagishi and Terachi, 1997). The Ogura CMS has recently been transferred into the small-rooted radishes to aid the production of F₁ hybrid seeds.

The breeding objectives for small-rooted radishes are quite different from those of the large-rooted types. For the small-rooted types, the most important trait is early bulbing. Such a trait prevents the swollen hypocotyl and root becoming pithy or “wooden” in texture, which makes the crop inedible for human consumption. Hence, breeders have focused on selecting for early growth, fast growth rate, and an annual cycle, which can be found in both *radicula* and early *niger* types of radish. These types of radishes do not require vernalizing temperatures to bolt but will flower especially under long days. For this reason, such types of radishes would not be suitable for summer cultivation. However, through selection, summer varieties, which exhibit decreased sensitivity to photoperiod, are on the market (Tsukamoto and Konishi, 1959). The small-rooted radishes are also commonly grown under glass during the winter season. Under conditions of poor light and warm temperatures, the net assimilation of the radish plant may be too low to allow thickening of the developing root and so the plant will bolt prematurely without the formation of a harvestable root. However, breeders have been able to overcome the problems of early bolting by conventional breeding (Banga and Van Bennekon, 1962).

In terms of the breeding of large-rooted radishes, farmers in China and Japan have mainly focused on the introduction of disease resistance genes. During the early 1950s, most of the radish crop in Japan was destroyed by radish yellows (Katano, 1952). This disease is caused by the casual organism *Fusarium oxysporum* f.

sp. *conglutinans* race 2, which infects a wide range of cruciferous vegetables causing vascular browning and premature leaf fall. Through intensive breeding programs, it was discovered that both the Chinese and Japanese radishes had a rich source of resistance genes against *Fusarium* (Hida and Ashikawa, 1985), but also toward *Albugo candida* (Williams and Pound, 1963) and some viruses (Shimizu *et al.*, 1963).

In Korea, the main breeding objective is to produce vegetables out-of-season. Korean varieties of radish are sensitive to low temperatures and bolt before reaching maturity, if grown during the autumn season. Breeders in Korea have attempted to transfer the late-flowering trait of the Japanese variety “Tokinashi” into Korean varieties to produce winter cropping varieties. During the late 1960s, a late-flowering hybrid was released to the market but its root was found to be too slender and soft textured (Lee, 1987). Although breeders were able to produce autumn cropping varieties in later trials, such varieties often bolted when cultivated during the summer.

1.5 Rationale for Transgenic Breeding

The conventional breeding of radish has been a major success. Over a course of several thousand years, the radish has emerged from being an oilseed crop to a plant producing a large diversity of root shapes and sizes with different flesh and skin colors. Despite the plant having an incompatibility system, breeders have been able to utilize this in the production of F₁ hybrid seeds and also through CMS. Over the last 40 years, breeders have been able to introduce disease resistance genes into the crop and been able to generate new varieties capable of growing under a wide range of climates and different seasons. However, one of the major drawbacks of the conventional breeding of radish is that such methods remain time consuming and labor intensive (8–12 years to produce a new variety). Over the last 30 years, a new “tool” has emerged that could potentially help to accelerate the output of new varieties, this being plant genetic engineering. The progress made toward the generation of new germplasms of radish by tissue culture and other gene transfer methods will be described.

2. DEVELOPMENT OF TRANSGENIC RADISHES

2.1 Tissue Culture Approach in Radish

A prerequisite for the production of transgenic plants in culture is to establish an efficient shoot regeneration system from cultured cells or plant organs. In the case of radish, early studies have shown that the crop has a poor responsiveness toward various culture media in terms of shoot production. Such studies revealed that plant regeneration via organogenesis from hypocotyls (Matsubara and Hegazi, 1990), embryogenic calli (Jeong *et al.*, 1995), and microspores (Lichter, 1989; Takahata *et al.*, 1996) showed a poor regeneration frequency. During the mid 1990s, studies focused on the use of ethylene inhibitors and polyamines in culture media to improve the shoot production of seedling explants of radish, as previous reports highlighted their benefits toward shoot production in related members of the Brassicaceae family. For example, the ethylene released by cultured explants of mustard appeared to impair shoot regeneration (Pua and Lee, 1995) and the inclusion of polyamines in culture media benefited the regeneration of shoots of Chinese cabbage cotyledon explants (Chi *et al.*, 1994). In the case of radish hypocotyls explants, the addition of silver nitrate and L- α -2-aminoethoxyvinylglycine (AVG) to the shoot regeneration medium N1B2 enhanced the shoot regeneration frequency to 40% (Pua *et al.*, 1996). In addition, the supplementation of the polyamine and putrescine at 10–25 mM in the presence of silver nitrate or AVG also greatly benefited the regeneration of hypocotyl explants on N1B2 medium. In a more recent study, the value of ethylene indirectly, polyamines, and gelling agent on the regeneration of hypocotyl and cotyledon explants of the radish Korean ecotype “Jin Ju Dae Pyong” were investigated (Curtis *et al.*, 2004). Using established regeneration media for hypocotyls (N1B2 medium) and cotyledons explants (CR medium; initially used for *B. napus* by Moloney *et al.*, 1989), a shoot regeneration system was established for this commercially important Korean ecotype. In terms of gelling agent, the use of 0.8% (w/v) agar was superior in promoting shoot regeneration in both explants compared to the 0.4% (w/v) agarose treatments (Figures 2a–d).

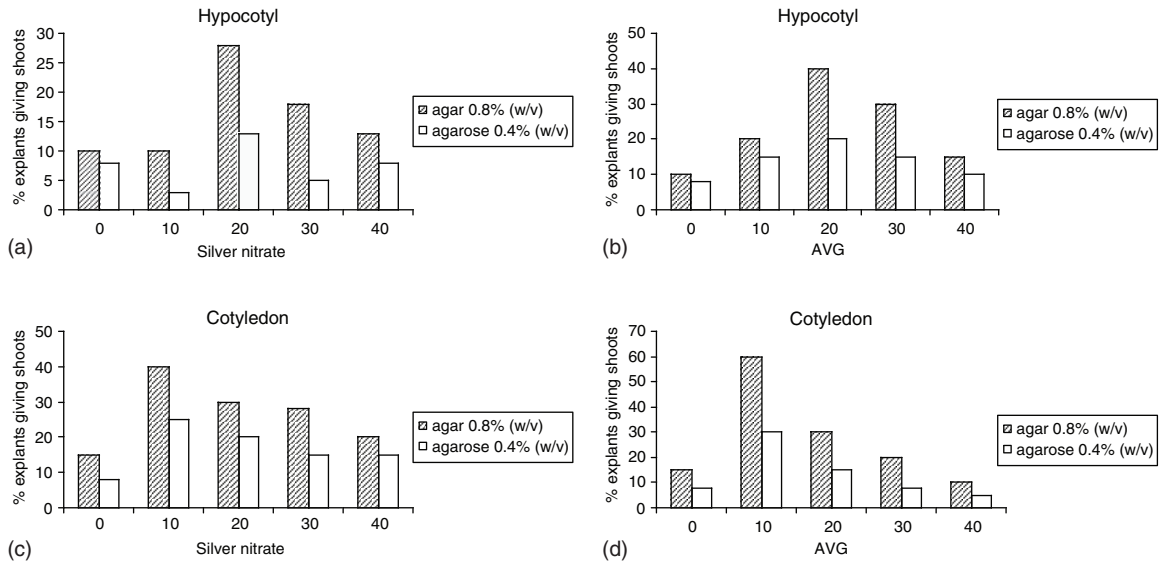

Figure 2 The effects of gelling agent, silver nitrate, and AVG on the regeneration of shoots from (a, b) hypocotyls and (c, d) cotyledon explants of the Korean ecotype “Jin Ju Dae Pyong”, 40 days after culture

This contradicted a previous study by Pua *et al.* (1996), who demonstrated that Chinese radish hypocotyl explants produced more shoots when cultured on agarose medium compared to agar medium. A possible reason why agar treatments were superior compared to agarose treatments for the study with Korean radish was that a highly purified agar was used and that any inhibitory cell growth components may have been removed. The supplementation of either silver nitrate or AVG was significantly better in promoting shoot regeneration compared to treatments without these agents for both hypocotyls and cotyledon explants. However, in terms of shoot production, the hypocotyl (20 μM, 40% regeneration frequency) and cotyledon (10 μM, 60% regeneration) explants required a different concentration of AVG for the optimal regeneration of shoots. Such improved regeneration frequencies for radish explants in culture should in the near future aid the possible production of transgenic radish plants in tissue culture.

In order to assess the usefulness of tissue culture as a means of producing phenotypically normal radish plants, tissue culture-derived plants, and seed-derived plants were compared (Curtis *et al.*, 2004). In this study, a population of 144

regenerated plants (74 from 1-month-old cultures, 70 from 3-month-old cultures) derived from hypocotyl and cotyledon explants from various treatments were compared phenotypically with 62 seed-derived plants under glasshouse conditions. Both populations of regenerated plants bolted and flowered earlier compared to seed-derived plants. In terms of pollen viability, wild type plants revealed more fluorescein diacetate-stained pollen grains (69.0 ± 10.0) compared to tissue culture-derived plants (1 month old, 53.8 ± 7.8 ; 3 months old, 38.9 ± 6.9). Regenerants from 3-month-old cultures (1772 ± 219 mg) yielded larger seed weights compared to plants from 1-month-old cultures (1301 ± 120 mg) and wild type (1490 ± 179 mg).

To be able to study the likelihood of alterations in chromosome number in regenerated plants, root tip squash preparations from 10 randomly selected R_1 lines (10 plants from each line) were hydrolyzed and stained according to the method by Dyer (1963). From 100 cell counts per plant from each line, between 85% and 90% of cells from seed-derived plants and 78–88% from 1-month-old shoot cultures had the same chromosome complement from the diploid number ($2n = 2x = 18$) (Figure 3a). However, plants derived from

Figure 3 Chromosome preparations from squashed root tips: (a) seed-derived plant exhibiting the normal 18 chromosome complement; (b, c) aberrant chromosome number from a R_1 plant derived from a 3-month-old culture with (b) 22 and (c) 36 mitotic chromosomes (bar = 10 μ m)

3-month-old shoot cultures were less synchronized in terms of number of chromosomes per cell compared to the other treatments. Between 50% and 80% of the cells from the 3-month-old shoot cultures exhibited between 20 and 40 chromosomes per cell (Figure 3b–c). To confirm whether root tip squashes were a good indicator for detecting ploidy in radish, leaves from selected 3-week-old plants were excised and analyzed by flow cytometry. Nuclei from such leaves were stained with 4'6-diamidino-2-phenylindole (DAPI) then passed through a particle analysing system (PAS)-type flow cytometer. These stained nuclei were analyzed in terms of the relative DNA content per nuclei. As a standard, leaves from seed-derived plants were set to 100 fluorescence units corresponding to the chromosome complement of diploid plants. Both wild type and plants derived from 1-month-old cultures produced a major peak at 100 fluorescence units (Figures 4a–b). In terms of the lines derived from 3-month-old cultures, two lines formed a major peak at 120 units (Figure 4c) and another independent line gave two major peaks at 100 and 120 units (Figure 4d). The seven remaining 3-month-old culture lines formed a peak at 100 units.

Further studies were performed on these R_1 lines to see whether plants with deviations in DNA content per nuclei also showed unusual phenotypes. The three R_1 lines with a relative DNA content per nuclei greater than wild type (Figures 4c–d) produced larger leaf areas compared to lines derived from 1-month-old cultures and wild type. However, the numbers of seeds produced by these three R_1 lines were significantly lower compared to wild type and the 1-month-old culture lines. This study demonstrated that prolonged culture of radish

explants can cause a higher turnover in the number of genetically variable plants. This observation supports a previous study in tobacco, where plants regenerated from protoplasts exhibited a higher frequency of ploidy following prolonged culture (Huang and Chen, 1988). Overall, this study in radish emphasized the need for a short culture period of explants to be able to produce phenotypically normal plants in culture and for the future of producing genetically stable transformants through *Agrobacterium*-mediated systems in tissue culture.

2.2 Somatic Hybridization

Plant protoplasts, a wall-less cell, can be used for several techniques directed at plant genetic manipulation. Such cells can be used as recipients for plasmid DNA and organelles including chloroplasts and mitochondria. One of the most important uses of protoplasts is that they can be induced to fuse, either chemically or through the use of electrical currents, with protoplasts of other species to produce a novel hybrid or somatic hybrid. This method allows sexually incompatible species to be combined at the genome level but also allow hybrid organelle combinations.

In terms of radish, the use of somatic hybridization has been mainly focused on transferring useful characters from radish into *Brassica* species (Sakai and Imamura, 1990; Hagimori *et al.*, 1992). This technology is useful as sexual hybrids between *R. sativus* and *Brassica oleracea* (*Raphanobrassica*) have limitations. Firstly, such sexual crosses can only be achieved, if radish is used as the female parent and so the cytoplasm of *B. oleracea* cannot be introduced into the hybrids. In addition, the

Figure 4 Relative fluorescence of nuclei stained with DAPI of (a) seed-derived plant and R_1 plants derived from (b) 1-month-old culture and from (c, d) 3-month-old cultures

fertility of *Raphanobrassica* is poor (McNaughton, 1973) and backcrossing to *B. oleracea* remains difficult.

One successful application of somatic hybridization using radish as a parent was the transfer of clubroot resistance into cauliflower (Hagimori *et al.*, 1992). Japanese radishes carry resistance to this root infection caused by the fungus

Plasmodiophora brassicae (Yoshikawa *et al.*, 1979). Somatic hybrids were produced after the electrofusion of iodoacetamide-treated cauliflower protoplasts with untreated radish protoplasts. From 40 regenerated plants, 37 were true hybrids based on phenotype, isozyme, and restriction fragment length polymorphism analysis. All hybrids exhibited resistance to clubroot disease equal to that of the Japanese radish.

Recently, somatic hybrids between *A. thaliana* ecotype Columbia and a male-sterile radish line MS-Gensuke were produced by fusing protoplasts of the two species with polyethylene glycol (Yamagishi and Glimelius, 2003). By using an established protoplast culture system for *Arabidopsis* (Yamagishi *et al.*, 2002), 11 shoots/rooted plants from a population of 41 shoots showed hybrid DNA patterns when analyzed at the molecular level. The chloroplast genomes of these hybrids were exclusively of radish origin but the mitochondrial DNA revealed a combination of both parental genomes. Those somatic hybrids, which flowered, were male-sterile regardless of the presence of the Ogura CMS gene *orf138*. This report offers the opportunity for the gene pool of radish to be expanded if such hybrids are backcrossed to radish. Such material would also be useful for studying nuclear–organellar genetic interactions as the *Arabidopsis* genome has been completely sequenced.

2.3 Production of Transgenic Plants by *Agrobacterium*-Mediated Gene Transfer

There is now a wealth of protocols that describe the production of transgenic crops. Such methods often rely on the culture of plant cells, tissues, or organs on complex media and then foreign DNA is transferred by *Agrobacterium*-mediated transformation or by biolistics. In the case of radish, the production of transgenic plants has been severely delayed due to the poor responsiveness of cultured explants to regenerate shoots. For this reason, researchers looked at alternative procedures of trying to produce genetically modified radish to widen the gene pool of this important crop. The production of transgenic radish was finally achieved by a nontissue culture method, which is classified as *in planta* transformation. Today, there are two *in*

planta transformation systems available for the production of transgenic radishes.

2.3.1 Floral dipping

The first report on the production of transgenic radish by *Agrobacterium*-mediated transformation was achieved by a method commonly known as “floral dipping” (Curtis and Nam, 2001). This procedure involves the dipping of a recently flowering plant into a container containing a surfactant, energy source, and the biological gene transfer agent *Agrobacterium tumefaciens*. The method itself is relatively simple and an experienced plant cell culturist is not required. One of the first reports on the use of *in planta* transformation involved *A. thaliana* L. (Bechtold *et al.*, 1993). In this report, the inflorescences of the plants were subjected to a vacuum during inoculation to aid transformation. A later investigation using *Arabidopsis* identified that the use of a vacuum was not necessary and the term “floral dipping” was employed (Clough and Bent, 1998). Subsequently, this technique has been used successfully in other plant systems including *B. rapa* L. ssp. *chinensis* (Qing *et al.*, 2000) and *Medicago truncatula* (Trieu *et al.*, 2000).

The success of using *in planta* transformation in the production of transgenic plants from the members of the Brassicaceae family encouraged researchers to investigate the usefulness of floral dip as a means of transforming radish (Curtis and Nam, 2001). *A. tumefaciens* strain AGL1 (Lazo *et al.*, 1991) was used in the study as the bacterial agent could transform seedling explants of the Korean variety “Jin Ju Dae Pyong” (Curtis, personal communication). This variety of radish was used in the investigation due to its commercial importance. The bacterial strain carried the binary vector pCambia3301, having the selectable marker for bialaphos resistance (*bar*) and the reporter β -glucuronidase (*gusA*) genes both under the control of the cauliflower mosaic virus (CaMV) 35S promoter located between the left and right transferred-DNA (T-DNA) borders, respectively. This dual-marker gene system would allow putative-transformed plants to be screened *in solium* through the use of herbicide sprayings and GUS expression to be monitored by histochemical staining. The concentration

of herbicide used, in this case Basta®, was determined experimentally by spraying different concentrations of the herbicide onto wild type plants and then monitoring the number of necrotic plants over a period of 30 days. Basta used at 0.03% (v/v) was the lowest concentration to cause necrosis on all wild type plants and so was used as the working concentration for selecting transformed plants. Unique to previous studies on *in planta* transformation, the effects of the type and concentration of surfactant used in the inoculation medium were studied in terms of transformation efficiency.

The floral-dip transformation system for radish has been described in detail (Curtis, 2004). Essentially, when radish plants are dipped into a suspension of *A. tumefaciens* containing a surfactant the plants are grown in the glasshouse and then hand pollinated to promote seed set. Prior to seed harvest, the origins of the seeds were noted from all plants. Following seed ripening, all seeds were sown in trays of compost. Plantlets were sprayed with herbicide at the four-leaf stage of development, then twice more at weekly intervals. Thirty days after sowing, all non-necrotic plants were deemed to be resistant to Basta and were subsequently assayed for GUS activity by histochemical staining to confirm their transgenicity.

In this same study, three stages of plant development were investigated in terms of their effect on transformation efficiency (Figure 5). These stages included plants exhibiting a primary bolt (single main stem with many immature floral buds), plants with branches from the main stalk (secondary bolts), and plants with side branches from the secondary bolts (tertiary bolts). In terms of the surfactants used in the inoculation medium, the presence of Silwet L-77, Pluronic F-68, and Tween 20 at concentrations 0, 0.01, 0.05, and 0.1% (v/v) were investigated. The study confirmed that the presence of a surfactant in the inoculation medium was necessary for the transformation of radish as treatments without the chemical failed to yield any transformants. Silwet L-77, a tri-siloxane, was the superior surfactant when used at 0.05% concentration in the inoculation medium. Primary bolted plants dipped into a suspension of *Agrobacterium* containing 0.05% Silwet L-77 and 5% sucrose (w/v) gave the optimal transformation efficiency of 1.4%

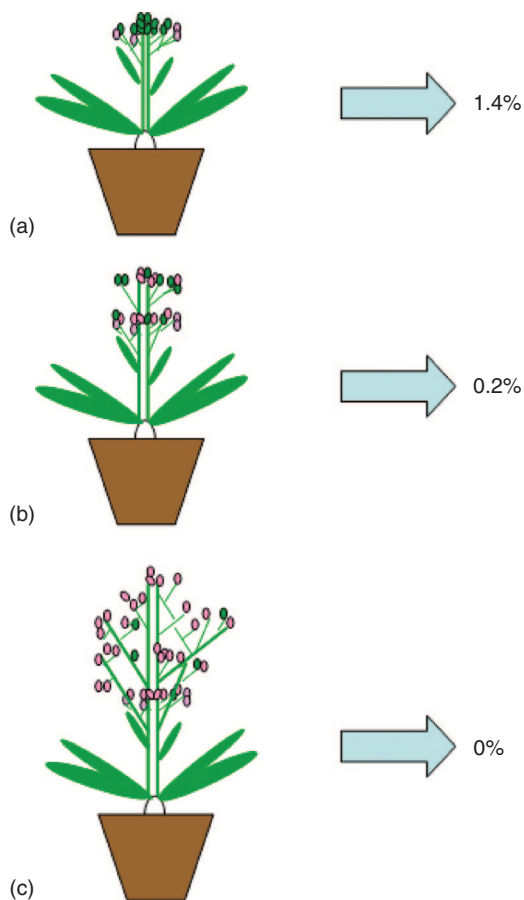

Figure 5 The effects of plant development on the transformation efficiency of the Korean ecotype “Jin Ju Dae Pyong” using floral dip; the three stages of development investigated were (a) primary bolt, (b) secondary bolted plant, and (c) tertiary bolt (percentage figures represent the optimal yield of transformed seeds with regards to the state of plant floral development at the time of dipping into inoculation medium)

(15 transformed seeds from a population of 1110). The stage of floral development of the dipped plant was found to be important in the transformation of radish. Tertiary bolted plants failed to produce any transformed seed regardless of which surfactant was present in the inoculation medium. Treatments involving secondary bolted plants gave a lower optimal transformation efficiency (0.2%) compared to primary bolted plants. Overall, this study confirmed that the ideal conditions for the transformation of Korean variety “Jin Ju Dae Pyong” was to dip primary bolted plants into a suspension of *Agrobacterium*

containing 5% (w/v) sucrose and 0.05% (v/v) Silwet L-77.

Molecular analysis of plants produced from the progeny of plants dipped into inoculation medium revealed some insight of the possible mechanism of how radish is transformed during floral dipping. Southern blot analysis showed that there were several populations of transformed plants with the same T-DNA insertion pattern, a phenomenon known as siblings. Observing the site where the seeds originated from the mother dipped plant, it was found that each individual population of siblings was derived from the same bolt. This discovery is very different from that of *Arabidopsis* as all transformed seeds are usually independent transformants (Clough and Bent 1998). However, studies made on a less-related plant, *M. truncatula*, revealed that between 77% and 87% of transformants were siblings (Trieu *et al.*, 2000). It has been postulated that *Agrobacterium* transfer their T-DNA into meristematic cells, which later develop into floral bolts (Trieu *et al.*, 2000). If such a meristematic cell is transformed, then that cell would carry the same T-DNA event into the whole developing bolt. However, in the case of *Arabidopsis*, the site of *Agrobacterium*-mediated transformation following floral dip is the ovule (Ye *et al.*, 1999; Desfeux *et al.*, 2000). Histochemical staining of pollen from several thousands of flowers from plants dipped into a suspension of *Agrobacterium* revealed no GUS activity and thus confirming that the pollen is not the site of transformation in radish. At present, the frequency of sibling transformants in radish following floral dip is between 50% and 60%. For this reason, researchers on radish improvement are now looking for alternative procedures to increase the yield of independently transformed plants.

2.3.2 Infiltration of germinating seeds

To date, there have been several reports on the transformation of recalcitrant plants through non-tissue culture approaches. During the late 1980s, it was reported that germinated seeds of *Arabidopsis* when co-cultivated with a disarmed *A. tumefaciens* strain carrying neomycin phosphotransferase II (*nptII*) gene resulted in treated plants producing seeds with resistance to the antibiotic (Feldmann

and Marks, 1987). Seeds imbibed for 12 h prior to being inoculated with *Agrobacterium* gave the highest transformed progeny. In a later study, this approach was also proved successful in the transformation of *M. truncatula* (Trieu *et al.*, 2000). In this particular study, seeds were imbibed and cold treated for 14 days prior to the seedlings being infiltrated with a suspension of *Agrobacterium* under vacuum. Following transferring these plants to the glasshouse, the number of transformants was determined in the following generation. The frequency of transformants ranged from 2.9% to 27.6% and, similar to the floral-dip procedure, such a population of transgenics was made up of independent transformants and sibling transformants. Southern analyses confirmed that the percentage of independent transformants arising from the seedling transformation was between 67% and 86% compared to 13% and 23% for the flower infiltration procedure. Although these two methods for transforming *M. truncatula* were successful for several strains of *Agrobacterium*, the widely used strain, LBA4404 failed to yield any transformed seeds. The seed yield from plants infiltrated at flowering and at seedling stage of development was poor compared to nontreated plants.

Sonication-assisted *Agrobacterium*-mediated transformation has been shown to improve the efficiency of *Agrobacterium* infection by introducing many small wounds into target plant tissues in soybean (Santarém *et al.*, 1998; Trick and Finer, 1998). In a recent study, examining the value of sonication followed by vacuum infiltration on germinated seeds in the presence of *A. tumefaciens* enabled transgenic radish plants to be produced (Park *et al.*, 2005). Seeds of radish cultivar “Kosena” were germinated on damp filter paper at 25 °C for 24 h in darkness. Germinated seeds were inoculated with *A. tumefaciens* strain LBA4404 carrying the *nptII* gene under the control of nopaline synthase (*nos*) promoter and terminator along the T-DNA. The inoculation was performed in a vessel with sonication for 0–12.5 min with a 2.5 min interval. Following sonication, the germinated seeds were placed into a vacuum chamber for 0–12.5 min. After vacuum infiltration, the seeds were blotted dry then co-cultivated in the dark at 25 °C for 3 days. Seeds were washed in Claforan®, washed in water, and then finally blotted dry prior to transfer to the soil.

After 4 weeks, the number of surviving plants was analyzed at the molecular level to determine their transgenicity. The optimal yield of transformed plants was obtained with the treatment comprising of a 5 min sonication period followed by a 5 min vacuum infiltration (8% transformation efficiency) as confirmed by polymerase chain reaction (PCR) and Southern blotting. Transformants carried 1 or 2 copies of the transgene and were derived from independent transformation events. This study confirmed that an alternative procedure exists for the production of novel germplasms of radish by an *in planta* method of gene transfer.

2.4 Transfer of Agronomic Traits into Radish

To date, two *Agrobacterium*-mediated transformation systems exist for the production of transgenic radish. These systems have recently been employed for the generation of important germplasms to improve the agronomic performance of this important crop.

2.4.1 Late flowering

Korean people are very proud of their own varieties of radish in terms of the root being hard, crisp in texture making this root crop the country's national vegetable. In terms of the percentage, growing area used for the cultivation of root crops in Korea, the cultivation of radish crop constitutes 85% of this total (Curtis, 2004). However, despite its popularity in Korea, such varieties are cold sensitive causing the cropping season to be restricted. Cool temperatures during the fall season (Figure 6a) results in the growth habit of the radish to change from a rosette plant to bolt and the root to become shrunk and inedible (Figure 6b). Although sexual crosses between cold-tolerant Japanese varieties and commercial Korean varieties produced late-flowering hybrids, such plants had poor textured roots (see Section 1.4). For this reason, other approaches were investigated to overcome this problem. Using the recently developed “floral-dip” technique for transferring foreign genes into radish (Curtis and Nam, 2001), such a system was investigated for the transfer of a late-flowering trait into the

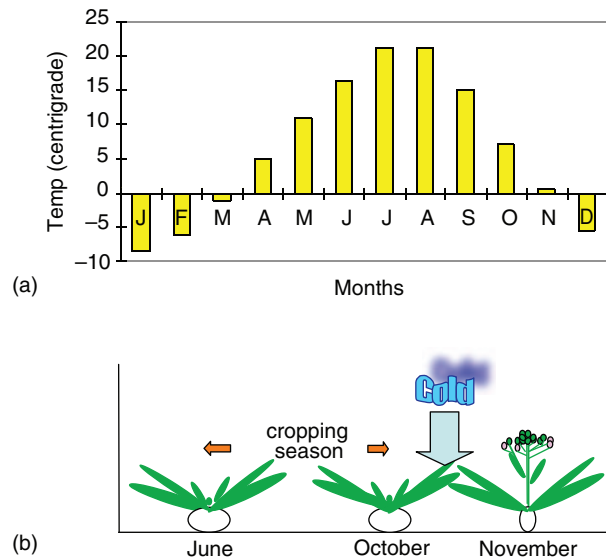

Figure 6 The restriction of cropping season of the native Korean radish due to cool temperatures: (a) average minimum temperatures in Suwon, a popular region for the cultivation of radish in Korea; (b) prevailing low temperatures in Korea restrict the cropping season from June to October

commercially important Korean variety “Jin Ju Dae Pyong”.

The change of the shoot apical meristem from the vegetative to the flowering form occurs in response to a change in the environment such as daylength (photoperiod) and reductions in temperature (vernalization). The genes involved in these developmental changes have been reviewed in substantial detail in the model plant *Arabidopsis* (Reeves and Coupland, 2000; Sheldon *et al.*, 2000). *GIGANTEA* (*GI*) is important in regulating photoperiodic flowering and controlling circadian rhythms (Fowler *et al.*, 1999; Park *et al.*, 1999). Several *gi* mutants have been identified in *Arabidopsis*, which exhibit photoperiod-insensitive flowering and a breakdown of the circadian clock (Koornneef *et al.*, 1991). Hence, under long days, such mutants exhibited delayed flowering time compared to wild type. In addition, overexpression of the *GI* gene under the control of the constitutive promoter, CaMV 35S, in *Arabidopsis* resulted in early flowering (Park, personal communication). These observations suggest that down-regulation in the expression of the *GI* gene may cause late flowering. In order to investigate whether a down-regulation in the expression of the native *GI* gene in radish could delay flowering, the model cultivar

“Jin Ju Dae Pyong” was transformed with an antisense *GI* gene under the control of CaMV 35S promoter by the floral-dip technique (Curtis *et al.*, 2002). *A. tumefaciens* strain AGL1 carrying pCambia3301 with an antisense *GI* gene from *Arabidopsis* was used in this study. From the seeds of 25 floral-dipped plants, a total of 16 T₁ plants were found to be transformed as confirmed by *in solium* selection, GUS staining and by Southern blot analysis. Northern analysis revealed that the expression of the *GI* gene in the antisense *GI* T₁ plants was much reduced compared to wild type and plants transformed with only *gus* and *bar* genes (positive control). The progenies of the antisense *GI* plants (T₂ generation) were compared phenotypically with wild type and positive control plants. All antisense *GI*-transformed lines showed a delay in bolting and flowering time compared to wild type and plants transformed with marker genes only (Figures 7a and b). The longest delay in bolting time by a T₂ antisense *GI* line compared to wild type was 17 days. In terms of time to anthesis (time to reach first flower opening), this same T₂ line showed a delay of 18 days compared to wild type. However, the heights of 10 of the 11 T₂ lines investigated, exhibited a significantly smaller height compared to wild type and positive

Figure 7 Phenotypic responses of T₂ plants of antisense *GI* transformants: (a–c) the times to (a) bolting, (b) flowering, and (c) the heights of transgenic and nontransformed plants is given as mean \pm standard error of the mean (plants A1, A8, A12, and A14 represent antisense *GI*-transformed lines; the control is the positive control line carrying *gusA* and *bar* genes; wild types are nontransformed plants)

control plants (Figure 7c). It is not clear whether a reduction in *GI* expression could affect stem elongation but further studies are necessary to confirm this observation. Nevertheless, this study demonstrated that by down-regulating the expression of *GI* in radish resulted in a delay in both bolting and flowering times, which ultimately could allow the growing season of this commercial variety to be extended into the autumn season.

2.4.2 Drought tolerance and salt stress

One of the main breeding objectives in radish is to produce roots out-of-season. Through the recent development of gene transfer systems now available for radish, such useful germplasm could be generated through the expression of drought and salt tolerance genes. One possible group of genes that could induce such tolerance are the late embryogenesis abundant (*LEA*) genes, which may be induced to high levels of expression by abscisic acid (ABA) and/or desiccation (Bray *et al.*, 2000). *LEA* proteins are classified into five major groups based on their amino acid sequence (Dure, 1993). In terms of their function, the wheat *LEA* protein was reported to act as an osmoprotective molecule in yeast (Swire-Clark and Marcotte, 1999). In addition, the expression of the *hva1* gene from barley, a group 3 *LEA* gene in rice (Babu *et al.*, 2004) and wheat (Sivamani *et al.*, 2000) further confirmed their value in providing tolerance to stress conditions in transgenic plants. In order to determine whether the expression of a group 3 *LEA* gene in radish could induce drought and salt tolerance, transgenic plants were produced through sonication and vacuum infiltration of germinated seeds (Park *et al.*, 2005).

In this report, *A. tumefaciens* strain LBA4404 carrying pBI121 with a group 3 *LEA* gene from *B. napus* was used in this study. The *LEA* complementary-DNA (cDNA) clone *ME-leaN4* was under the control of the CaMV 35S promoter with an *nptII* gene linked to a NOS promoter and terminator sequence. Studies on drought tolerance and salt stress were performed on the progeny of plants (T₁ generation) from the *Agrobacterium*-inoculated seedlings. Seeds from transgenic lines were sown on semi-solidified

Murashige and Skoog (MS, Murashige and Skoog, 1962) medium containing 50, 100, 200, 300, and 400 mM mannitol to study osmotic stress. For the salt stress experiment, seeds were sown on MS medium supplemented with 50, 100, and 150 mM NaCl. Following 10-days culture at 25°C under a 16 h photoperiod, both the length and fresh weight of plantlets were compared with nontransformed plants. Transgenic plants cultured on medium containing 50–300 mM mannitol exhibited a faster growth rate compared to nontransformed plants. In terms of the salinity stress experiment, the transgenic lines showed a longer plant length and a greater fresh weight for the treatments 50–150 mM NaCl compared to wild type. These experiments implied that the *LEA* gene from *B. napus* improves the tolerance of radish to both water deficit and salt stress in culture.

3. FUTURE ROAD MAP

3.1 Expected Products

Due to the recent developments of two gene transfer systems for radish, namely, “floral dip” (Curtis and Nam, 2001) and the infiltration method into germinated seeds (Park *et al.*, 2005), one expects an increase in the production of novel germplasm in this crop. Over the last 5 years, such methods of producing transgenic plants have resulted in a late-flowering Korean radish (Curtis *et al.*, 2002) and the transfer of drought and salt tolerance (Park *et al.*, 2005). In terms of future products, the large-sized 3-month-old radishes from Asia has the attraction through gene technology of expressing antibodies or synthetic vaccines, which would have value in the Third World where the crop is extensively cultivated. In addition, the complete nuclear and organellar genome sequences of *Arabidopsis* (Unsel *et al.*, 1997; Sato *et al.*, 1999; The Arabidopsis Genome Initiative, 2000) and the future determination of their function will allow a host of useful traits to be transferred from a related plant into radish. Here, an alternative strategy of producing a late-flowering radish will be discussed using a novel approach by a chemical-inducible promoter system, which has recently been achieved in the model plant *Arabidopsis* (Curtis *et al.*, 2005).

The production of a late-flowering Korean radish offers the possibility of the growing season

to be extended into the autumn season. Expression of an antisense *GI* gene in radish resulted in bolting and flowering time to be extended by a few weeks compared to wild type (Curtis *et al.*, 2002). However, phenotypic characterization of T₂ plants showed that the down-regulation of endogenous *GI* could affect other plant-development processes including plant height. In a recent report, delayed bolting and flowering time in *Arabidopsis* was achieved through the site-specific inactivation of gibberellin (GA) through the expression of a GA 2-oxidase gene from bean *PcGA2ox1* under the control of an estrogen inducible system, XVE bacterial repressor LexA (X), the acidic transactivating domain of VP16 (V) and the regulatory region of the human estrogen receptor (E; ER) (Zuo *et al.*, 2000). A single application of 17- β -estradiol, an analogue of estrogen, to the apical shoot of rosette plants of *PcGA2ox1* overexpressors showed delay in bolting (46 days) and flowering time (62 days) compared to wild type (36 and 41 days, respectively). Quantitative reverse transcription (QRT)-PCR results showed that GA down-regulated genes were up-regulated and that GA up-regulated genes were down-regulated in a site-specific manner. These results suggest that the *PcGA2ox1* under the control of an estrogen-inducible promoter could delay bolting and flowering time by localized 2 β -hydroxylation. Future research is needed to investigate whether such a system could be applied to crops, such as radish, which may result in a further extension of the growing season in commercial Korean varieties, especially if repeated applications of inducer are used.

3.2 Addressing Risks and Concerns

Recent advances in the transfer of novel genes into crops by genetic manipulation techniques have created new possibilities for crop improvement. However, the introduction of genetically modified crops into field trials opens the possibility of transgene escape into the environment via pollen dispersal. The concern, as with all genetically modified crops, is the likelihood and consequence of a transgene being transferred through pollen dispersal to wild relatives or nontransgenic crops. For pollen-mediated gene transfer to occur, pollen from transgenic plants must be dispersed toward

such plant populations and successfully fertilize an ovule. Transgenes for herbicide, insect, disease, and stress resistances could benefit weeds to become a new troublesome problem for farmers and affect the ecological balance in natural habitats (Darmency, 1994).

Studies on the hybridization between radish and other related plants in the field have focused on sexual crosses between oilseed rape (*B. napus*) and a wild radish, *R. raphanistrum*. Such reports have mainly focused on the possibility of transgenic pollen from *B. napus* being used to fertilize wild radish to produce hybrid seed (Darmency *et al.*, 1998; Chevre *et al.*, 2000; Guéritaine and Darmency, 2001; Rieger *et al.*, 2001). Wild radish is a self-incompatible species (Sampson, 1964) and so cannot produce seeds by itself. Early studies using *B. napus* as the seed parent produced partially fertile hybrids with *R. raphanistrum* but hand pollination and embryo rescue were necessary (Kerlan *et al.*, 1992). In the field, a large amount of hybridization was reported when a male-sterile *B. napus* was used (Chevre *et al.*, 1996). However, experiments conducted under commercial agronomic conditions showed that two from over 52 million seedlings from male-fertile *B. napus* were hybrids with wild radish (Rieger *et al.*, 2001). This study confirmed that under field conditions there is a very remote possibility (4×10^{-8}) of hybridization from pollen of wild radish fertilizing fertile oilseed rape.

Wild radish is considered to be within the top 100 economically damaging weeds worldwide. Recently, there have been concerns from environmentalists that biotechnology companies should refrain from releasing transgenic radishes to the field to avoid resistances to viruses, insect pests and herbicides being transferred into this troublesome weed. In a report produced at the University of California, researchers studied the incidence of gene flow from cultivated radish into wild radish using a test plot (N. Ellstrand, personal communication). Cultivated radishes were grown in the center of a field surrounded by a population of wild radishes. The cultivated radish carries a dominant marker *Lap6* gene, which is present as a recessive trait in wild populations. Thus, to monitor gene flow from the cultivated radish to wild populations was based on the presence or absence of this marker in the progeny of wild radish. All plants analyzed 1 m away from the

cultivated radish population produced a hybrid carrying the allozyme allele. In addition, the presence of the allele was also detected up to 1 km away from the cultivated crop. In terms of seed yield, the hybrid population produced 15% more seeds compared to the wild radish. Although this is the only study using both cultivated and wild radishes together in a field trial, there appears to be genuine concern that transgenes may be released into wild radish and appropriate management strategies need to be enforced to prevent the production of so-called “super weeds”.

3.3 Expected Technologies

Over the last 20 years, advances in gene technology have enabled a wide diversity of crop species to be successfully transformed. In the case of radish, the poor responsiveness of cultured explants to regenerate shoots was a major stumbling block toward generating transgenic plants through tissue culture approaches. However, the application of *in planta* systems toward the transfer of agronomic useful traits has allowed important novel germplasms to be created at transformation efficiencies up to 8% being reported (Park *et al.*, 2005). However, it is not clear how applicable such technologies would be to a wider gene pool of radish germplasms. At present, only two varieties of radish have been successfully transformed by *in planta*-mediated transformation techniques. One possible area for both widening the accessibility of radish varieties to be transformed and also improving transformation efficiency is through a tissue culture-based system. Over the last 10 years, there have been major improvements in the regeneration of seedling explants through the use of ethylene inhibitors in culture (Pua *et al.*, 1996; Curtis *et al.*, 2004) and shoot regeneration frequencies of up to 60% have recently been reported (Curtis *et al.*, 2004). At present, the major delay in the production of transgenic plants in culture has been the mismatch between a useful shoot regeneration system and the incorporation of a gene transfer system. Radish seedling explants are not amenable to shoot regeneration in the presence of antibiotics in the culture medium (Curtis, personal communication). However, the use of a nonantibiotic selection system may circumvent the problem.

The use of a nonantibiotic gene-marker system in radish may not only improve the transformation efficiency of radish in culture but also allow the future release of transgenics into field trials and prevent the possibility of “super weeds” being produced. One possibility is the use of the mannose-based positive selection system, which has been used successively for cassava (Zhang *et al.*, 2000). This system is based on the use of the phosphomannose isomerase (*pmi*) gene from *E. coli* being used as a selectable marker and mannose as the selectable agent. In nontransformed plant cells, mannose is phosphorylated by a hexokinase to mannose-6-phosphate, which can significantly impair cell growth. Cells carrying the *pmi* gene can convert mannose-6-phosphate to fructose-6-phosphate, which can be used as a carbon source and enabling transformed cells a metabolic advantage. Plants transformed with the *pmi* gene offers no risk to human, animal and the environment.

There is now a level of optimism in terms of improving the agronomic performance of radish by gene technology. If further commercial varieties of radish prove to be amenable to transformation then one expects the crop to enter field trials soon and provided appropriate management strategies are employed the crop should not pose a risk to the environment.

DEDICATION

This work is dedicated to the 2.5 million people who lost their lives during the North Korean famine of the mid 1990s. Radish is a major crop in North Korea and the work on the genetic improvement of the crop underlines the importance of genetic engineering to improve crops for the Third World.

1. INTRODUCTION

1.1 History, Origin, and Distribution

Carrot (*Daucus carota*) is a biennial crop, grown as an annual for its edible tap root. Eastern or Asiatic carrots are often called anthocyanin carrots due to their purple roots and are found predominantly in Russia, Afghanistan, Iran, and India. They are believed to be the ancestor of Western or Carotene-type carrot (Quiros, 2001). Domestication is thought to have taken place in these areas around the 10th century and the Carotene types were developed during the late 16th century and early 17th century. Orange-, red-, or white-rooted biennial carrots were derived from the Eastern types most likely through selection of hybrid progenies of yellow carrots and wild subspecies grown in the Mediterranean (Quiros, 2001). Farmers in the Netherlands were the first to cultivate orange carrots and today's cultivars are thought to have originated from varieties developed there (Rubatzky and Yamaguchi, 1997).

1.2 Botanical Description

Carrot is a monocarpic herb and a member of the family Apiaceae (formally Umbelliferae) (Pressman, 1997; Rubatzky and Yamaguchi, 1997). Native to Europe and parts of Asia, *D. carota* consists of 13 subspecies divided into two groups,

the Carota and Gingidium (Quiros, 2001). The Carota group contains the cultivated species (var. *sativum*). Wild forms of the Carota group are widespread throughout the world (var. *carota*). All subspecies of *D. carota* can cross freely with each other (Quiros, 2001).

1.3 Economic Importance

In excess of 13.5 million tons of carrot is grown for human consumption (FAOSTAT, 2006), accounting for approximately 3% of the world's vegetable production and considered one of the most important vegetables (Hardegger and Sturm, 1998). Carrot is the third most important vegetable crop produced in Australia after tomatoes and potatoes, comprising 8% of the value of Australia's total vegetable production (Seven Vegetables, 2000). In 2004, Australia produced 302 560 t of carrots on 73 195 ha with a production rate of 420 514 hg ha⁻¹ with an average export value of US\$432.18 per ton (FAOSTAT, 2006).

Victoria is Australia's highest carrot producing state, producing 113 310 t in 2002, predominantly for the local market (Australian Horticulture Statistics Handbook, 2004). Western Australia is Australia's leading exporter of fresh carrots, accounting for approximately 90% of the country's carrot exports (McKay and Pasqual, 2006). In 2002/2003 Western Australia produced 88 211 t of carrots and exported in excess of 75 000 t (Australian Horticulture Statistics Handbook,

2004). Western Australia's largest carrot export market is Malaysia, followed by Singapore and the United Arab Emirates (McKay and Pasqual, 2006; Australian Horticulture Statistics Handbook, 2004). Important carrot varieties in Australia are Nantes type, Ivor, Stefano, Red Count, and Crusader (McKay and Pasqual, 2006). Nantes type carrots (blunt-ended, straight to slightly tapered roots) are the most commonly grown variety Australia wide (Seven Vegetables, 2000).

The β -carotene content in the storage roots makes carrot a highly nutritious food source (Rubatzky and Yamaguchi, 1997; Hardegger and Sturm, 1998). Responsible for the orange color of storage roots, β -carotene is cleaved into two vitamin A molecules during digestion (McKay and Pasqual, 2006). Carrot is also an excellent source of sugar, vitamin C, and fiber (Quiros, 2001). The mature storage organ of a carrot comprises 88% water, 6–8% sugar, 1–2% fiber, 0.7–1.2% protein, 1% ash, and 0–3% fat (Hardegger and Sturm, 1998). Glucose, fructose, and sucrose make up total sugar content (Peterson and Simon, 1986). Of commercial interest are cultivars with a high yield, a high sugar level, and high resistance to pests and diseases (Peterson and Simon, 1986). As well as using carrot raw, cooked, canned, frozen, pickled, or dehydrated, carotene can be extracted for use as food coloring in margarine, or in poultry feed to intensify skin and egg yolk color (Rubatzky and Yamaguchi, 1997).

1.4 Traditional Breeding: Breeding Objectives, Tools, and Strategies

Genetic improvement of *D. carota* has been previously achieved through plant breeding (Simon, 1984; Peterson and Simon, 1986; Ammirato, 1996). Carrot hybrids are most often generated via three-way crosses and selection is made via the root to seed method (Quiros, 2001). Cultivated carrots are classified into two major groups, temperate and subtropical, with breeding efforts focused on temperate types due to their higher value and larger market share. Temperate carrot types include Nantes, Imperator, Danvers, and Chantenay and the subtropical class includes Kurada, Brasilia, and Tropical Nantes types (Quiros, 2001).

Madjarova and Bubarova (1983) were the first to investigate the application of genetic crosses for improved root color. More recently, breeding for specific characteristics such as male sterility (Nothnagel *et al.*, 2000), bolting resistance, and disease and pest resistance (Bonnet, 1983; Boiteux *et al.*, 1993, 2004) have become a priority. Other important traits being introduced into carrot genotypes are improved flavor, eating quality and color and increased carotene content (Quiros, 2001).

Sufficient genetic variation may exist among cultivated classes of carrot to derive any root type or regional adaptation; however, crosses between domesticated and wild-type carrots and subsequent backcrosses have been necessary to introduce pest and disease resistance in elite breeding lines (Quiros, 2001). Tissue culture techniques such as *in vitro* anther culture (Ammirato, 1996), somaclonal variation (Sung and Dudits, 1981; Ammirato, 1996), and protoplast fusion (Sung and Dudits, 1981) have been used to enhance resistance to pests and diseases.

1.5 Limitations of Conventional Breeding

Pathogenic and environmental pressures on modern crop production practices have increased as a result of broadening growing regions outside those that plants are naturally adapted to. Conventional breeding technology has historically enabled breeders to develop more robust plant genotypes that incorporate genes and hence traits of interest. However, some argue that dwindling genetic resources are making conventional breeding practices increasingly difficult (Quiros, 2001). Where no feasible natural biological method is available, alternative methods must be developed to enable crop improvement and overcome specific abiotic and biotic stress. Genetic transformation has been developed as an attractive tool for the transfer of useful traits into genetic backgrounds lacking those traits. By incorporating the genetic material that provides the trait into the plant genome, the favorable trait can be passed onto the plant's progeny. This technology has been widely exploited to obtain commercial crops with improved agronomic traits.

2. DEVELOPMENT OF TRANSGENIC CARROTS

2.1 Transformation Methods Employed

A variety of techniques exist for the direct introduction of new genetic material into carrot host cells. These include electroporation (Fromm *et al.*, 1985), chemicals that increase uptake of DNA (Paszowski *et al.*, 1984), microinjection (Crossway *et al.*, 1986), and DNA delivery via microparticle bombardment (Klein *et al.*, 1987). However, it is widely believed that *Agrobacterium*-mediated transformation has distinct advantages over direct transformation methods (Horsch *et al.*, 1985; de la Riva *et al.*, 1998). *Agrobacterium*-mediated transformation of plant tissue generally results in a low transgene copy number and minimal rearrangements compared to direct transformation methods, potentially leading to fewer problems with transgene co-suppression and instability (Flavell, 1994; Koncz *et al.*, 1994; Hansen *et al.*, 1997; Vaucheret *et al.*, 1998). Direct transformation frequently gives rise to mosaic plants, whereas *Agrobacterium*-mediated transformation, being a single-cell transformation system, avoids this problem (Enriquez-Obregón *et al.*, 1998). It is also believed that a higher transformation efficiency can be achieved by using *Agrobacterium*-mediated transformation (Pawlowski and Somers, 1996; Gelvin, 1998).

Carrot was first reported to be susceptible to infection by *Agrobacterium* wild-type strains and disarmed strains of *Agrobacterium tumefaciens* by De Cleene and De Ley (1974). Subsequently, from the late 1980s onwards, carrot tissues have been routinely transformed with *A. tumefaciens* strains (Hardegger and Sturm, 1998). The development of *Agrobacterium*-mediated transformation during the late 1980s and early 1990s, opened up the potential for the genetic manipulation of carrot phenotypes. Using *Agrobacterium*-mediated technology, the selectable marker gene neomycin phosphotransferase (*nptII*), conferring kanamycin resistance or the reporter gene β -glucuronidase (*GUS*), was introduced and expressed in carrot genomes (Scott and Draper, 1987; Liu *et al.*, 1992; Gilbert *et al.*, 1996; Hardegger and Sturm, 1998; Tang and Sturm, 1999). The use of antibiotic resistance genes and reporter genes allowed studies on the factors affecting transformation efficiency.

Hardegger and Sturm (1998) also made direct comparisons between two *A. tumefaciens* strains harboring different genetic backgrounds (LBA4404: Ach5 and GV3101: C58) and binary plasmids containing the *nptII* gene conferring resistance to kanamycin. Although in this instance hypocotyl segments of 7-day-old seedlings were inoculated with *A. tumefaciens*, the transformation efficiency was high for both strains following 2 days of co-cultivation (Hardegger and Sturm, 1998). Interestingly, inoculation of callus cells with LBA4404 was 20 times less effective than GV3101 (Hardegger and Sturm, 1998), indicating that the use of different *A. tumefaciens* strains results in variable transformation efficiencies dependent on the plant tissue type inoculated.

Many reports exist for the successful transformation of carrot tissues, however, only four state transformation efficiencies (Scott and Draper, 1987; Wurtele and Bulka, 1989; Liu *et al.*, 1992; Hardegger and Sturm, 1998), making it difficult to draw meaningful comparisons. Generally though, for *Agrobacterium*-mediated DNA transfer, selection of transformed cells with the antibiotic kanamycin and plant regeneration via somatic embryogenesis have been the preferred methods (Scott and Draper, 1987; Wurtele and Bulka, 1989; Balestrazzi *et al.*, 1991; Pawlicki *et al.*, 1992).

2.2 Transgenes and Transgenic Traits

One of the first reports of carrot transformation described the high-frequency transformation of carrot proembryogenic suspension culture with a Ti-plasmid vector carrying a kanamycin resistance gene (Scott and Draper, 1987). Transformed tissues expressed readily detectable levels of *nptII* as confirmed by Western blotting (Scott and Draper, 1987). In an effort to improve transfer-DNA (T-DNA)-mediated transformation, Liu *et al.* (1992) investigated the effect of multiple copies of *virG* genes contained in *A. tumefaciens* strains on the transient transformation of carrot tissue. Histochemical GUS assays determined that multiple copies of *virG* in *A. tumefaciens* greatly enhanced the transient transformation of carrot calli (Liu *et al.*, 1992). Hardegger and Sturm (1998) investigated transformation efficiency of different cell types and tissues of carrot using *A. tumefaciens*

harboring a binary vector that contained the *GUS* marker gene and the *nptII* gene. They found the highest T-DNA transfer rates were achieved by co-cultivating bacteria with hypocotyl segments and subsequent regeneration of somatic embryos via liquid culture (Hardegger and Sturm, 1998).

The ability to induce somatic embryos from carrot tissue and the application of embryos in transformation systems have recently led to the development of transgenic carrot genotypes with resistance to *Erysiphe heraclei* and *Alternaria dauci* (Takaichi and Oeda, 2000), and *Botrytis cinerea* and *Sclerotinia sclerotiorum* (Chen and Punja, 2002; Punja and Chen, 2004). Herbicide tolerance (Chen and Punja, 2002) and resistance to viral infections (Zheng *et al.*, 2002) have also been developed in carrot genotypes using the somatic embryogenesis/*Agrobacterium*-mediated transformation partnership. *Agrobacterium* was also employed to incorporate an edible vaccine for the measles virus (Marquet-Blouin *et al.*, 2003) and to increase calcium content (Park *et al.*, 2004). For this, a range of explant tissue types, *Agrobacterium* strains, and antibiotic selection regimes were used.

Although there are many reports of carrot transformation that provide a sound basis for future transformation experiments, they are generally genotype specific. The development of optimal conditions for co-cultivation and regeneration as well as the use of an optimal type and concentration of a selectable marker is required for each carrot genotype.

2.3 Whole Plant Regeneration

Somatic embryogenesis was first identified in cultures of *D. carota* tissue derived from the storage tap root by Steward *et al.* (1958) and Reinert (1958, 1959). Since 1958, a substantial number of investigations involving somatic embryogenesis in carrot cultures of various tissue types in both wild and cultivated species have been undertaken (Nomura and Komamine, 1986; Wake *et al.*, 1995). Subsequently, somatic embryogenesis has become the 'model system' for carrot regeneration because embryogenic cultures can be easily obtained and regenerated (Komamine *et al.*, 1992).

For the rapid production of large numbers of plants, where spatial constraints exist, the greatest potential of clonal multiplication is through

somatic embryogenesis, with a single isolated cell possessing the ability to produce an embryo then a complete plant (Taji *et al.*, 1997). Minocha and Minocha (1995) reported the potential for multiplying millions of superior plants using this method of asexual propagation for both horticultural and forestry crops. Combined with genetic engineering, tissue culture through somatic embryogenesis provides an efficient means of producing a large number of elite or transgenic plants (Osuga and Komamine, 1994).

Carrot tissue is readily manipulated *in vitro*, thus has been used for decades as a 'model system' for regeneration via somatic embryos (Quiros, 2001). Regeneration from carrot callus cultures, via somatic embryogenesis, has been achieved from seedling-derived hypocotyl tissues (Kamada and Harada, 1978; Takaichi and Oeda, 2000; Jiménez and Bangerth, 2001; Chen and Punja, 2002), mature petiole tissue (Drew, 1979), and root tissue (Smith and Street, 1974; Kitto and Janick, 1985). Somatic embryogenesis can be divided into an auxin-requiring (embryo induction) and an auxin-inhibited (embryo expression) stage for carrot and most other plants (Nissen and Minocha, 1993; Jiménez and Bangerth, 2001) and a basic three-step formula has been found to be successful for the induction of somatic embryos and regeneration of whole carrot plants from callus. Firstly, callus is induced from explant material incubated in the dark on Murashige and Skoog (MS) (1962) nutrient medium supplemented with the auxin 2,4-dichlorophenoxyacetic acid (2,4-D) (Figure 1), most often at 5 μ M (Kamada and Harada, 1978; Kitto and Janick, 1985; Jiménez and Bangerth, 2001; Chen and Punja, 2002). A low level of kinetin in combination with 2,4-D was also shown to successfully induce callus in root, petiole, and hypocotyl explants (Smith and Street, 1974; Drew, 1979; Kitto and Janick, 1985; Chen and Punja, 2002).

The second step is embryo maturation and proliferation following excision of callus from explant material, also an auxin-requiring stage (Figure 2). This was achieved from root and hypocotyl explants on an auxin-rich medium (Fujimura and Komamine, 1975, 1979; Nomura and Komamine, 1985; Roustan *et al.*, 1989; Nissen and Minocha, 1993; Nissen, 1994; Munksgaard *et al.*, 1995; Jiménez and Bangerth, 2001; Ceccarelli *et al.*, 2002; Chen and Punja, 2002),

Figure 1 Four-week-old petiole explants with varying amounts of callus initiation

and on a medium containing both auxin and cytokinin in similar concentrations (Smith and Street, 1974; Drew, 1979; Kitto and Janick, 1985). Although suspension culture is often used for proliferation of callus cultures (Smith and Street, 1974; Fujimura and Komamine, 1975; Kamada and Harada, 1978; Drew, 1979; Fujimura and Komamine, 1979; Kitto and Janick, 1985; Nomura and Komamine, 1985; Roustan *et al.*, 1989; Nissen and Minocha, 1993; Nissen, 1994; Munksgaard *et al.*, 1995; Ceccarelli *et al.*, 2002; Chen and Punja, 2002), other published methods include the use of solid medium for callus proliferation and maintenance (Smith and Street, 1974; Kitto and Janick, 1985; Jiménez and Bangerth, 2001).

The third step is germination or regeneration of embryos and subsequent growth into plantlets. This step has been most commonly achieved for carrot via the removal of auxin from the nutrient medium (Smith and Street, 1974; Drew, 1979; Kitto and Janick, 1985; Roustan *et al.*, 1989; Nissen, 1994; Jiménez and Bangerth, 2001;

Takaichi and Oeda, 2000; Chen and Punja, 2002), although the inclusion of 0.5 μM zeatin in the nutrient medium has resulted in successful embryo regeneration (Fujimura and Komamine, 1975, 1979; Fujimura *et al.*, 1980; Nomura and Komamine, 1985). Kamada and Harada (1978) reported that 5 μM 2,4-D was successful for regeneration of plantlets from a callus intermediary via somatic embryos, which contradicted the commonly held belief that auxins inhibited somatic embryogenesis (Nissen and Minocha, 1993; Jiménez and Bangerth, 2001). Germination of somatic embryos has been achieved on both MS (Murashige and Skoog, 1962) and Lin and Staba (1961) nutrient media, while regeneration was achieved using both suspension and solid medium culture.

3. FUTURE ROAD MAP

3.1 Risks and Concerns

Before commercial release, the potential risks of genetically modified carrots must be evaluated using an integrated multidisciplinary approach incorporating molecular biology, toxicology, nutrition, and genetics (Kuiper *et al.*, 2001). Safety considerations include: the effects of any production processes applied to the novel food; the effect of the genetic modification on the properties of the host organism; the genetic stability of the modified organism used as the source of the novel food; the specificity of expression of the novel genetic material, and the ability of the modified organism to survive in and colonize the human gut microflora. The anticipated intake and extent of the use of the novel food; nutritional information, allergenicity and toxicological information, and

Figure 2 Somatic regeneration of carrot cv. Crusader

ecological impact must also be considered (Kuiper *et al.*, 2001; GMO Compass, 2006). Any potential risks of genetically modified carrots should be compared with the associated environmental benefits. It has been proposed that the increase in adoption of insect-resistant and herbicide-resistant corn, cotton, and soybean crops resulted in 8.2 million fewer pounds of active pesticide used in 1998 compared to 1997 (USDA, 2000).

Novel technologies are continually being developed which are addressing potential risks associated with genetically modified food. Potential risks such, as horizontal gene flow associated with the use of antibiotic selectable markers, are subject to controversy (Kuiper *et al.*, 2001). Recently, a gene linked to kanamycin resistance in *Arabidopsis* was discovered and was proven as a robust selectable marker for plant transformation (Rommens, 2006). The plant origin of this resistance gene, opposed to the bacterial origin of the *nptII* kanamycin resistance gene, has advantages from a public perception point of view (Rommens, 2006). Public survey has shown that consumers would be more likely to eat a vegetable that contains an extra plant gene rather than one that contains a gene from an alternate source (Lusk and Sullivan, 2002; Rozin, 2005). Alternatively, gene excision systems such as cre/lox are providing a means of removing superfluous genes following the introduction of expression cassettes into plant genomes (Wang *et al.*, 2005).

3.2 Public and Industry Perspectives

The success in creating transgenic carrot lines has created new considerations for further assessment and future commercial release. Although high-value crops such as maize, cotton, and canola form the majority of genetically modified food and feed authorized worldwide, horticultural crops are also being assessed and grown commercially (FDA, 2006; GMO Compass, 2006; OGTR, 2006). In the European Union, which has 84 genetically modified crops registered at present, potato varieties with altered starch composition and sugar beet with herbicide tolerance are currently being assessed (GMO Compass, 2006). The United States currently has 98 bioengineered foods registered, including insect-resistant tomatoes, male-sterile radicchio, potatoes resistant to

Colorado potato beetle, cantaloupe with delayed fruit ripening and virus-resistant potato, squash, and papaya (FDA, 2006).

Australia currently has 65 genetically modified organisms or genetically modified products under examination or approved for intentional release by the national biotechnology governing body, the Office of Gene Technology Regulator (OGTR, 2006). Of these only two, namely insect-resistant cotton and color-modified carnation are currently being grown commercially (OGTR, 2006). In 2003, national regulatory approval was given for the release of herbicide-resistant canola (OGTR, 2006), however, a number of Australian state governments imposed moratoriums of commercial planting of this crop (OGTR, 2006). Australia, together with Europe, has been slow to approve commercial planting of transgenic crops compared to both Canada and the United States (Linacre *et al.*, 2006). Australia has planted only 0.2 million hectares of transgenic crops, principally insect-resistant cotton (Linacre *et al.*, 2006), whereas Canada and the United States have 4.4 and 42.8 million hectares, respectively of transgenic crops under cultivation (James, 2003). The regulatory framework currently employed to approve commercial releases in Australia is believed to be one reason for the slow approval rate of transgenic crops (Linacre *et al.*, 2006), however, public perception concerning the risks associated with genetically modified food still remains a major hurdle for further release of transgenic crops (Biotechnology Public Awareness Survey, 2003).

1. INTRODUCTION

1.1 *Cucurbita* Species

1.1.1 History, origin, and distribution

There are five cultivated species of the genus *Cucurbita*. These include *C. pepo*, *C. moschata*, *C. maxima*, *C. argyrosperma*, and *C. ficifolia*. Because most of the wild species of *Cucurbita* are found in Mexico in an area extending south of Mexico City to the border with Guatemala, this area is considered as the center of origin or distribution of the genus (Whitaker and Robinson, 1986; Robinson and Decker-Walters, 1997).

The most extensively cultivated species is *C. pepo* and, therefore, much more is known about its origins and areas of domestication than the other cultivated species. *C. pepo* is indigenous to North America and consists of numerous subspecies and varieties (Andres, 1987; Wilson, 1990). This crop was probably independently domesticated in Mexico and the eastern United States between 10 000 and 30 000 years ago (Decker, 1988; Smith *et al.*, 1992). The current view of the infraspecific taxonomy of the species has been developed by Decker-Walters and coworkers (Decker, 1988;

Decker-Walters *et al.*, 1993; Decker-Walters *et al.*, 2002): Pumpkins, marrows, and some of the ornamental gourds belong to *C. pepo* ssp. *pepo*, while cultivated crookneck, scallop, and acorn squashes as well as most of the ornamental gourds belong to *C. pepo* ssp. *ovifera* var. *ovifera*. Free-living (i.e., noncultivated) forms are placed in other taxa. The free-living populations in Texas belong to *C. pepo* ssp. *ovifera* var. *texana*; free-living populations occurring in the Mississippi Valley and the Ozark Plateau belong to *C. pepo* ssp. *ovifera* var. *ozarkana*; free-living populations occurring in northeastern Mexico belong to *C. pepo* ssp. *fraterna*.

While cultivated *C. pepo* can be found throughout the world wherever the climate is suitable, and escaped populations may become established, free-living populations naturally occur in North America from northeastern Mexico and in the United States from Texas to Alabama, through the Mississippi Valley to Illinois (Smith *et al.*, 1992; Cowan and Smith, 1993). Some of these free-living populations can occur as weeds in soybean and cotton fields especially in Arkansas, Louisiana, and Mississippi (Oliver *et al.*, 1983; Boyette *et al.*, 1984; Smith *et al.*, 1992; Bryson and Byrd, 1998). There is anecdotal evidence that the advent of genetically engineered herbicide tolerant

soybean and cotton has reduced the weed problem posed by these weedy populations of *C. pepo*.

Numerous studies have documented the present and historical ability of free-living and cultivated populations to exchange genes (Kirkpatrick and Wilson, 1988; Smith *et al.*, 1992; Decker-Walters *et al.*, 1993, 2002). Other studies have shown that some free-living populations may have been the result of individuals that have escaped from cultivation, became established, and subsequently have crossed with other nearby cultivated or free-living populations (Decker and Wilson, 1987; Wilson, 1990; Asch and Asch, 1992; Cowan and Smith, 1993; Decker-Walters *et al.*, 1993).

1.1.2 Botany

Cucurbita is considered to be one of the most morphologically variable genera in the plant kingdom (Robinson and Decker-Walters, 1999). *Cucurbita* cultivars are categorized as summer squash or winter squash. Summer squash are eaten immature when tender and seeds are small and soft. Winter squashes are generally eaten when rind and seeds are fully mature. Summer squash cultivars are *C. pepo* while winter squash cultivars can be *C. pepo*, *C. maxima*, *C. moschata*, or *C. argyrosperma*.

Variation in fruit shape within *C. pepo* is the basis for 10 horticultural classifications of this species (Paris, 1986, 1996). These include eight edible-fruited cultivar groups designated pumpkin, vegetable marrow, cocozelle, zucchini, acorn, scallop, crookneck, and straightneck and two nonedible-fruited ornamental cultivar groups designated orange gourd and ovifera gourd. Pumpkin cultivars produce round, spherical, globular, oblate, ovate, obovate fruit shapes; smooth or warted, with or without longitudinal grooves, ribs, or furrows. Fruit rind color of this group varies from orange to green; solid in color to those with stripes. Vegetable marrow has short, tapered cylindrical fruit with a length-to-width ratio of 1.5–3.0. Rind colors include yellow, orange, light to dark green, solid or striped. Fruit can be smooth to warty. Cocozelle has cylindrical, long fruit with length-to-width ratios of greater than 3.5. Rind colors range from light to dark green, solid or striped with some ribbing. Zucchini

is uniformly cylindrical, or nearly so, with a length-to-width ratio of 3.5–5.0. It is considered to be the most popular *C. pepo* cultivar. The most common rind color is green but brilliant yellow cultivars are available since the introduction of the precocious yellow gene. Acorn is turbinate in shape with deep furrows, broad at the peduncle end and convex at the styler end. Rind colors include white, orange, yellow, green, tan that are solid, striped, or blotched. Scallop fruit, also known as pattypan, is flattened disk shaped with scalloped margins. Rind colors include white, yellow, orange, and green, solid or variegated. Crookneck cultivars produce fruits that are elongated with slight to very curved necks and broad blossom ends. Straightneck cultivars, derived from crooknecks, produce fruits with shorter and straighter necks. The rind color of crooknecks and straightnecks are predominantly yellow. The two ornamental gourd groups include various shapes and colors, mostly bitter and inedible. The botanical and horticultural classifications of *C. pepo* have been integrated. *C. pepo* L. subsp. *pepo* contain the pumpkin, vegetable marrow, cocozelle, zucchini, and orange gourd groups, while *C. pepo* L. contain the acorn, crookneck, scallop, straightneck, and ovifera gourd groups.

There is considerable morphological diversity in *C. moschata* with regard to its seeds and fruit color, shape, and thickness of rind (Bates *et al.*, 1990; Robinson and Decker-Walters, 1999). Horticultural groupings based on market-type cultivars include neck, cheese, tropical, and japonica. The neck group produces fruits that are curved or straight, have an enlarged blossom end, and the rind is usually buff colored. Cheese-type cultivars produce fruits that are oblate in shape and buff colored. Fruits of the tropical group are round or irregularly shaped with buff, yellow, green, spotted or patchy, solid or bicolored rinds. The japonica group is generally bluish-black in rind color, warty, and wrinkled.

C. maxima exhibits the greatest diversity of fruit types after *C. pepo* (Bates *et al.*, 1990; Robinson and Decker-Walters, 1999). Several horticultural groups based on market type describe this species based on fruit shape, color, or size. These include Australian blue, banana, buttercup, Hubbard, mammoth, and turban. Australian blue are blue-rinded squash produced mainly in Australia. Fruit size and shape vary. The banana group produces

fruits that are elongated, tapered at the stem, and blossom ends. Rind color varies from orange and light to dark green. The buttercup group has small drum-shaped fruit with a “button” or protuberance at the blossom end. Rind colors include deep orange to dark green. The Hubbard group produces oval fruit, tapering to curved necks at both ends. Fruits are smooth or warty and range in color from orange, green, and gray. The mammoth group produces mainly orange fruits that are 100 pounds or more and grown for exhibition at contests. Cultivars in the turban group are similar to buttercup but the protuberance at the blossom end is more prominent. The rind of this group is very colorful.

Cultivars of *C. argyrosperma* and *C. ficifolia* are produced primarily for their seed, which provides a considerable amount of oil and protein. Both these species are produced and consumed in Central America.

1.1.3 Economic importance

Cucurbita species (pumpkin, squash, and gourds) are grown throughout the temperate, subtropical, and tropical regions of the world. They collectively rank among the top 10 vegetable crops produced worldwide with nearly 1.6 million ha devoted to production (FAO, 2006). In 2005, approximately 20 million metric tons of pumpkin, squash, and gourds were produced; an increase of almost 15% compared to 2000. China and India lead the world in production providing close to 30% and 18% of the world output, respectively. Other major producers include Ukraine, the United States, Egypt, Mexico, Cuba, Iran, Italy, and South Africa.

Cucurbita spp. are most often grown for human consumption of their fruits (Paris, 1989; Bates *et al.*, 1990; Robinson and Decker-Walters, 1999). Summer squashes are generally eaten immature when fruits are relatively small and tender, requiring no cooking for use in salads, or they can be boiled, fried, or microwaved. Winter squashes are eaten mature and can be baked, boiled, or microwaved. Both summer and winter squashes are low in saturated fat, cholesterol, and sodium, and are a good source of dietary fiber, vitamins, and minerals (NutritionData, 2006). Fruits with yellow or orange flesh generally

have high concentrations of carotenes, some of which are the precursors of vitamin A (e.g., β -carotene) and play a significant role in human nutrition, especially in tropical countries where their consumption is high. *C. moschata* and *C. maxima* cultivars producing fruits with the strongest flavor, highest soluble solids, and deepest flesh color are preferred for canned and frozen winter squash. The commercially canned pumpkin pie mix is made up of *C. pepo*, *C. maxima*, or *C. moschata* cultivars. Deep orange, carotene-rich fruits of *C. moschata* and *C. maxima* are processed for use in the baby food industry. The stringy flesh of *C. ficifolia* can be boiled to create “angel’s hair” candy. In the United States, various sized and shaped pumpkins are traditionally carved for Halloween festivities in the autumn.

In addition to the fruit, other parts of *Cucurbita* plant are edible (Bates *et al.*, 1990; Robinson and Decker-Walters, 1999). Seeds can be eaten whole, roasted, or toasted, and are a good source of protein, vitamins, and minerals. *Cucurbita* seeds can also be ground into a paste or pressed for vegetable oil. The oils of squash generally contain 40–60% linoleic acid, 20–40% oleic acid, 10–20% palmitic acid, and 0–15% stearic acid. The shoots, leaves, and tendrils of *Cucurbita* plants can be eaten as greens. Recipes using *Cucurbita* staminate and pistillate flowers, harvested on the day of or day after anthesis, are used in many countries.

1.1.4 Breeding achievements

Breeding of *Cucurbita* in the past has played a key role in the variety and productivity of cultivars available to growers and consumers today (Bates *et al.*, 1990; Robinson and Decker-Walters, 1999). Several examples include disease resistance (based on inter- and intraspecific hybridization), bush (short internode) plant habit, precocious yellow fruit pigmentation, and the development and introduction of specific varieties based on growers’ and consumers’ preferences. Genetic engineering has been used in this species to introduce commercial virus-resistant varieties (Quemada and Tricoli, 1992, 1995; Tricoli *et al.*, 1995, 2002).

Interspecific hybridization to transfer disease resistance alleles from wild to cultivated species of *Cucurbita* has proven beneficial. *Cucurbita ecuadorensis* is resistant to a number of viruses,

including zucchini yellow mosaic virus (ZYMV), the watermelon strain of papaya ringspot virus (PRSV-W), and watermelon mosaic virus (WMV) (Cutler and Whitaker, 1969). Multiple virus-resistant *C. maxima* cultivars derived from *C. ecuadorensis* have been developed at the Cornell University, USA, since 1985. “Redlands Trailblazer” and “Dulong QHI”, winter squash resistant to ZYMV, WMV, and PRSV, were bred in Australia from the same interspecific cross (Herrington *et al.*, 2001). Certain interspecific *Cucurbita* crosses can be difficult to obtain (Whitaker and Robinson, 1986). These difficulties can be overcome by embryo rescue methods or by use of a bridging species; e.g., crossing *C. pepo* to the hybrid of *Cucurbita okeechobeensis* with *C. moschata*. By using the hybrid of *C. okeechobeensis* with *C. moschata*, resistance to cucumber mosaic virus (CMV) and powdery mildew has been transferred from *C. okeechobeensis* to *C. pepo* and *C. moschata*. Intraspecific hybridization has also proven to be beneficial especially with regard to virus resistance. High levels of resistance to ZYMV, PRSV-W, and WMV were identified in a landrace of *C. moschata* “Nigerian Local” (Munger and Provvidenti, 1987). This source of virus resistance has been successfully introgressed into *C. moschata* and *C. pepo* cultivars.

Bush (short internode) plant habit, conferred by the allele *Bu*, in cultivars of summer and winter squash has maximized growing space and ease of harvest. In *C. pepo*, the *Bu* allele is incompletely dominant during the latter stage of development (Shifriss, 1947). In *C. maxima*, the *Bu* allele is completely dominant during early growth but loses this effect during the latter stage of growth (Grebenscikov, 1958). Denna and Munger (1963) characterized the bush habit in both *C. pepo* and *C. maxima*, and found it to be allelic in both species. Many cultivars of *C. pepo*, *C. moschata*, and *C. maxima* with a bush plant habit are available to growers.

Precocious yellow fruit pigmentation from a bicolored gourd (Shifriss, 1981), expressed by the allele *B*, has been bred into crookneck and straightneck squash and zucchini squash (*C. pepo*). Introgression of this gene, along with several modifiers (*Ep-1*, *Ep-2*, and *Ses-B*), results in fruit with a very deep yellow golden color and high vitamin A content. Another benefit of the *B* allele is in its ability to mask the unsightly green ringed

fruit symptoms of WMV. Fruits from WMV-infected plants can still be marketed compared to other nonprecocious yellow summer squash.

In addition to the traditional plant breeding methods of transferring virus-resistance alleles from wild to cultivated species of *Cucurbita*, scientists have genetically engineered virus resistance into squash (Quemada and Tricoli, 1992, 1995; Tricoli *et al.*, 1995, 2002). The first commercially available transgenic cucurbit was “Freedom II” (Asgrow Seed Co.), a yellow crookneck summer squash (*C. pepo*). *Agrobacterium tumefaciens* was used to transfer the coat protein genes of WMV and ZYMV into this crookneck squash. In 2004, 10% of the squash acreage grown in the United States was biotechnology derived, providing a little over 19 million dollars in revenue (Sankula *et al.*, 2005).

Breeding achievements of *Cucurbita* include the introduction of specific varieties or cultivars based on grower and consumer preferences (Bates *et al.*, 1990; Robinson and Decker-Walters, 1999). The following are just a few examples. Butternut-type (*C. moschata*) squash with consistent fruit size and shape, buff-colored rind, deep orange flesh, and disease tolerance is now grown and consumed throughout the United States. This winter squash was originally selected from the heirloom cultivar “Canada Crookneck” for bell-shaped fruit and introduced by the Breck Seed Company in 1936. Another butternut-type squash, “Waltham Butternut” (*C. moschata*), has been very popular since its introduction in 1970. This butternut was obtained from crossing “New Hampshire Butternut” with an African plant introduction producing fruit of greater uniformity, shape and color, and better flavor. The acorn squash “Table Queen” (*C. pepo*) was introduced in 1913 by Iowa Seed Company, and is believed to have been selected from a Native American landrace. This vine winter squash produces a smooth dark green ribbed rind with deep orange sweet flesh. Acorn squash cultivars with similar fruit shape and color, but with bush plant habit, have since been bred (e.g., Table Ace). “Delicata”, a *C. pepo* within the acorn group introduced by Peter Henderson Company in 1894, is still grown in both home gardens and commercially. Its cylindrical fruits are cream colored with green strips and their flesh is fine grained, sweet, and starchy. “Vegetable Spaghetti” is a member of the

vegetable marrow group of *C. pepo*, originating in northern Manchuria and first commercialized by Sakata Seed Company in 1934, and then in the United States in 1936. This yellow oval fruit when cooked produces thin fibrous strands resembling spaghetti. Yellow crookneck and straightneck summer squash (*C. pepo*) are very popular in the United States. “Early Prolific Straightneck” was introduced by the Ferry Morse Seed Company in 1938 and is said to have been derived from “Summer Crookneck”, which is listed in seed catalogs as early as 1807. Zucchini (*C. pepo*) is now considered the most consumed squash in the world. First introduced in Italy around 1901, it found its way to the United States in 1918. Since then, it has been bred for fruit uniformity, quality, and disease resistance. With the identification of the precocious yellow fruit pigmentation gene, *B*, working in concert with several modifying genes, a yellow-colored zucchini was bred and appeared on the market as “Golden Zucchini” in 1973. Other golden-type zucchini are now available to home gardeners and commercial growers.

1.1.5 Current breeding efforts

The goal of *Cucurbita* breeding programs is to release new cultivars having elite combinations of many desirable horticultural characteristics (Robinson and Decker-Walters, 1999). These desirable traits include earliness, increased productivity or yield, environmental adaptation, resistance or tolerance to diseases and pests, small, upright, open plant habit, shortened internode length for reduced vining or for bush plant habit, spineless foliage, consistent fruit shape and color, high fruit gloss, a small blossom scar, peduncles that separate easily from fruit or easily fracture away from fruit, and enhanced nutritional value such as β -carotene.

Many of the desirable characteristics of *Cucurbita* have complex inheritance and are influenced by a number of genes and their interactions (Robinson and Decker-Walters, 1999). Breeding to select for traits of importance requires population development, appropriate experimentation, and statistical analyses to understand the genetics governing these traits. Mass, recurrent, and pedigree selection as well as backcross breeding methods have been employed successfully to

introgress desirable traits into summer and winter squash and continue to be used in breeding programs (Munger *et al.*, 1993).

The development of hybrid cultivars instead of open-pollinated cultivars has been a major change in breeding summer and winter squash. This change has resulted in cultivars that can be harvested earlier and exhibit uniformity in fruit shape, as well as increased yield (Robinson and Decker-Walters, 1999). Current trends in breeding also include the use of wide crosses within or among species to identify beneficial genes. Wild *Cucurbita* species and germplasm in gene banks continue to be evaluated as important sources of resistance to pathogens and pests, variation in fruit and plant characteristics, and nutrition.

1.1.6 Genetics

Cucurbita species have 20 pairs of chromosomes ($2n = 2x = 40$), more than any other species in the *Cucurbitaceae*. Many *Cucurbita* genes and alleles have been identified and a list of genes has recently been published (Paris and Brown, 2005). A limited number of linkage maps exist for *Cucurbita* species. On the basis of an F_2 population derived from *C. maxima* and *C. ecuadorensis*, Weeden and Robinson (1986) were the first to create a linkage map containing 11 isozyme loci placed in five linkage groups. In 1995, Lee developed a map based on random amplified polymorphic DNA (RAPD) markers of a *C. pepo* \times *C. moschata* F_2 population consisting of 28 markers placed in five linkage groups. No morphological traits were included. Recently, a BC_1 population derived from *C. pepo* and *C. moschata* was used to develop a map placing five morphological traits and 148 RAPD markers in 28 linkage groups (Brown and Myers, 2002). This map covered 1954 cM, which is estimated to be 75% of the *Cucurbita* genome. Compared to other cucurbit genera such as *Citrullus* (watermelon) and *Cucumis* (cucumber and muskmelon), additional genetic linkage maps of *Cucurbita* species are needed to facilitate breeding efforts and increase our knowledge of *Cucurbita* genetics. Markers linked to genes that control fruit quality or confer resistance to diseases and pests are still required. A combination of traditional breeding methods and biotechnology

will likely play an important role in the genetic improvement of summer and winter squash.

1.2 *Cucumis* Species

1.2.1 History, origin, and distribution

1.2.1.1 Melon

Melon (*Cucumis melo* L.; $2n = 2x = 24$) is a member of the economically important family *Cucurbitaceae*. Molecular markers have been used in melon for genetic diversity analysis, elucidation of taxonomic relationships, determination of sites of origin and domestication, assessment of market class relationships in different melon backgrounds, and the definition of melon taxonomic groups and market classes (Stepansky *et al.*, 1999; Akashi *et al.*, 2002; Monforte *et al.*, 2003). Although the center of origin for *Cucumis* species is likely Africa for the wild species, initial sites of domestication for melon are likely in the Middle East (Dane *et al.*, 1980). During its domestication, melon received wide use and was distributed from points of origin along well-defined trade routes (e.g., the Silk Road and international shipping routes) (McCreight *et al.*, 1993; Robinson and Decker-Walters, 1997). Wild and feral *C. melo* populations can still be found in Africa, America, Asia, Australia, Europe, and the Pacific Islands (Jeffrey, 1980; Kirkbride, 1993).

1.2.1.2 Cucumber

Cucumber (*Cucumis sativus* var. *sativus* L.; $2n = 2x = 14$) may have originated in Africa, China, India, or in the Near East with domestication occurring later throughout Europe (Tapley *et al.*, 1937; Harlan, 1975). It was domesticated about 3000 years ago, and is indigenous to India (primary center of diversity; Jeffrey, 1980). Genetic relationships among accessions with regard to geographical origin are consistent with the generally accepted historic dispersal patterns of cucumber (Horejsi and Staub, 1999). Being initially domesticated in either India or Africa, cucumber was carried to the Middle East, then to the Mediterranean, and finally to Europe (Tatlioglu, 1993). Cucumber was brought to Greece and Italy by the Romans (2nd century

BC; Mesopotamia), and it appeared in France in the 9th century, in England in the 14th century, and in North America by the mid-16th century. The Spanish brought cucumber to Haiti in 1494, and cucumber was reported in Montreal, Canada (by Cartier), in Florida, US (by Desoto), and in Virginia, US (by Amidas and Barlow) in 1535, 1539, and 1584, respectively (Robinson and Decker-Walters, 1997; Lebeda *et al.*, 2006).

1.2.2 Botanical description: taxonomy, habit, genome size, and cytological features

1.2.2.1 Melon

In 1753, Linnaeus coined the genus name, *Cucumis*, and classified five cultivated melons as independent species (Stepansky *et al.*, 1999). Subsequently, Naudin (1859) made the first detailed classification of *C. melo*, and divided it into nine tribes of cultivated melons and one tribe consisting of wild forms. More recently, *C. melo* classifications were performed mainly by Russian researchers at the Vavilov Institute in the early 20th century (Stepansky *et al.*, 1999; Pitrat *et al.*, 2000).

The extensive morphological variation found in *C. melo* has led botanists to propose numerous infraspecific taxonomic classifications during the last 150 years (Stepansky *et al.*, 1999; Pitrat *et al.*, 2000). By modern consensus, melon belongs to the *Cucurbitaceae*, which is subdivided into two subfamilies, Zanonioideae and the Cucurbitoideae (Jeffrey, 1980; Kirkbride, 1993; Eurosid I clade of the Rosids). The latter subfamily is further partitioned into eight tribes of which the Melothrieae includes the genus *Cucumis*. *Cucumis* is partitioned into two subgenera designated as *Cucumis* ($2n = 2x = 14$ and 24) and *Melo* ($2n = 2x = 24$) that contain five cross-sterile species groups (Jeffrey, 1980). *Melo* ($x = n = 12$), the second subgenus, is divided into two sections (Melo and Aculeatosi). Section Melo contains four series (Humifructuosi, Melo, Hirsuti, Metulifrei, Angurioidei, and Myriocarpi) (Kirkbride, 1993). Series Melo houses melon and series Metulifrei contains metuliferus ("horned cucumber").

Melon consists of a diverse array of morphotypes differing in leaf, vine, plant, and fruit characters. Wild and cultivated melon in the

series Melo is subdivided into two subspecies that is based on assessments of Jeffrey (1980) according to the flower ovary hairiness. Typically, ssp. *melo* (cultivated) has lanate ovaries while ssp. *agrestis* (wild) has sericeous ovaries. According to ovary morphology, Munger and Robinson (1991) subdivided *C. melo* L. into ssp. *agrestis* (Naud.) Pangalo and ssp. *melo*. Based on their classification, ssp. *melo* is currently further subdivided into six cultivar groups including: (1) Cantalupensis—cantaloupe or muskmelon; (2) Inodorus—winter melons, honeydew, casaba; (3) Flexuosus—snake melon; (4) Conomon—pickling melon; (5) Chito and Dudaim—mango melon, vine peach, and other similar names for the former; pomegranate melon, Queen Anne's Pocket melon for the latter; and (6) Momordica—"phut" or snap melon.

Group Cantalupensis (e.g., Earl's, House, Galia, Charentais, and Ogen), Group Inodorus (e.g., Honeydew and Casaba), and Group Conomon (e.g., Oriental) have differing fruit morphologies and are valued worldwide for their unique flavor, aroma, and variable shelf life. While groups Cantalupensis and Inodorus are of commercial importance in the United States and Europe as well as in Mediterranean and Asian countries; group Conomon types have their origin and are widely grown in Asia (McCreight *et al.*, 1993; Robinson and Decker-Walters, 1997; Lebeda *et al.*, 2006).

1.2.2.2 *Cucumber*

Cucumber belongs to the subgenus designated as *Cucumis* ($2n = 2x = 14$ and 24 ; Jeffrey, 1980). The subgenus *Cucumis* comprises three or four Sino-Himalayan species, including *C. sativus* ($2n = 2x = 14$) and *Cucumis hystris* Chakr. ($2n = 2x = 24$). *C. sativus* consists of several botanical varieties including var. *sativus*, the cultivated cucumber (hereafter referred to as *C. s.* var. *sativus*), and the wild, free-living var. *hardwickii* (R.) Alef. (hereafter referred to as *C. s.* var. *hardwickii*) (Kirkbride, 1993). Wild African *Cucumis* species (mostly $2n = 2x = 24$) are cross-incompatible with cucumber and melon, which are themselves cross-incompatible (Kroon *et al.*, 1979). Likewise, the wild, free-living *C. hystris* is only sparingly fertile with cucumber (Chen *et al.*, 1995, 1997a, b). This

species is found only in the Yunnan Province of Southern China, and has unique genetic attributes that make its taxonomic determination complex.

1.2.3 Economic importance

1.2.3.1 *Melon*

Melon is the most economically important member of the *Cucurbitaceae*. Worldwide, more than 18 million metric tons of melons were produced in 1999, with China, Turkey, Iran, the United States, and Spain being the major producers (FAO, 1999). In the United States in 2003, over 1 million tons of Western Shipping and Eastern Market type melons, having a market value of almost 400 million US dollars, were produced (NASS, 2003).

The horticultural groups Cantalupensis (i.e., cantaloupe) and Inodorus (i.e., honeydew) are of particular commercial importance in the United States, Europe, and Asia (McCreight *et al.*, 1993). Although historic production records for some major growing areas are not available, consumption of cantaloupe has increased steadily in the United States, reaching approximately 5.5 kg per person in 2001. In contrast, demand for honeydew melon in the United States has fluctuated from 0.5 to 1 kg per person between the late 1970s and 2001.

In the United States, the Western Shipping and Eastern Market cantaloupe types of the Cantalupensis group are commercially the most important, being primarily grown in Arizona, California, Texas, Georgia, and Indiana (NASS, 2003). In 2003, US farmers grew more than 36 450 ha of cantaloupes for a total production in excess of 1 million tons and having a market value of almost 400 million US dollars. Cantaloupe yield in the United States has increased from 3 t ha⁻¹ in 1992 to 4.6 t ha⁻¹ in 2003.

1.2.3.2 *Cucumber*

After tomato and watermelon, cucumber and melon are cultivated more broadly than any other vegetable species. Approximately 2 427 436 ha of cucumber were harvested in 2004 producing 40 860 985 t under field and greenhouse culture

(FAO, 2004). Production of cucumber is the second largest of all cucurbits, with China (553 Mcwt or 25 084 080 t), Iran (30 Mcwt or 1 360 800 t), Turkey (38 Mcwt or 1 723 680 t), and the United States (23 Mcwt or 1 043 280 t) representing 71% of the world production in 2003.

Cucumber usage in the United States has climbed steadily since the 1960s, reaching 4.4 kg per capita in the 1990s (NASS, 1998). Average annual farm value was \$361 million (~2.4 billion kg) during 1997–99. Production of US fresh market cucumber (about 60% of all cucumber production) is highest in Florida, Georgia, California, and Michigan. In 1997, approximately 26 000 ha of fresh market cucumbers were harvested having a total value of \$185 194 000. These production levels have been maintained, and Michigan, Florida, North Carolina, Texas, Ohio, California, and Wisconsin continue to lead the production of pickling (processing) cucumber (33% used in fast foods).

1.2.4 Traditional breeding: breeding objectives; tools and strategies; and achievements

1.2.4.1 Melon

Melon quality has been improved specific to market demands and culinary practices depending on market class. Most of the yield improvement in melon (as with cucumber) can be credited to cultural practices, breeding for relatively simple traits such as resistance to diseases and pests, and the use of hybrids created from sparingly few elite lines (McCreight *et al.*, 1993; Robinson and Decker-Walters, 1997; Lebeda *et al.*, 2006). Continued yield and quality increases in melon will depend on the preservation, availability, and use of genetic variability (e.g., exotic germplasm), and breeding for quantitative traits that are directly related to yield.

Common breeding methods for population improvement of quantitative traits (e.g., fruit yield and quality) involve recurrent selection in diverse populations where gain from selection is made through mass or more structured family (half- or full-sib) selection. For introgression of qualitatively inherited traits (e.g., disease resistance, sex expression) simple backcross

and/or pedigree selection are often employed. For instance, studies assessing the superiority of hybrids and sex expression (important in hybrid seed production) are common, and by simple backcrossing procedures have resulted in the current predominance of melon hybrids in cultivation (Robinson and Decker-Walters, 1997; Rubatzky and Yamaguchi, 1997).

Disease resistance, high yield, and uniform fruit shape, size, and excellent quality are prerequisites for the release of superior melon varieties. Breeding for resistance to diseases (i.e., bacterial, fungal, and viral) and pests (e.g., aphids, beetles, and white flies) as well as for excellent quality melons (e.g., high sugar content, acceptable shape, and size) have been priorities of melon improvement programs (Robinson and Decker-Walters, 1997; Rubatzky and Yamaguchi, 1997; Lebeda *et al.*, 2006).

Historically, group *Cantalupensis* market classes have been uniformly enhanced by increasing carotene and sugar content, as well as improving internal (e.g., seed cavity size and total soluble solids) and external (fruit size and shape, netting) morphological attributes. Few studies, however, have investigated the genetics of yield or its components (e.g., days to anthesis, plant architecture, yield, and fruit maturity) (Lippert and Legg, 1972; Lippert and Hall, 1982). Quantitative trait loci (QTL) for external and internal traits have, however, recently been identified and mapped (Périn *et al.*, 2002a, b, c; Monforte *et al.*, 2004).

Yield- and quality-associated traits in melon are quantitatively inherited and typically have low heritability (Zalapa *et al.*, 2006). Thus, selection for yield often requires extensive evaluation over multiple years, locations, and replications. Indirect selection for yield and quality using correlated traits (i.e., fruit yield and quality components) has been successfully used for the improvement of several crop species, but has not been extensively applied to melon. Andrus and Bohn (1967) reported that in a heterogeneous cantaloupe melon population that had undergone nine generations of mass selection for a selection index including 18 fruit traits, the mean values for most characters increased without any apparent loss in genetic diversity. Furthermore, inbred lines developed from advanced mass selection cycles performed better for the selected fruit characters than inbreds

Figure 1 Melon (*Cucumis melo* L.) plant architectural types: dwarf indeterminate (vining; a), standard indeterminate with mainly distal fruit set (vining; b), crown set on fractal type indeterminate (vining; c), and internode differences among standard indeterminate and dwarf indeterminate (vining; d)

developed from earlier cycles. Subsequently, they studied pair-wise correlations among the 18 fruit characters under mass selection, and concluded that negative and positive correlations exist among these fruit characters studied (Bohn and Andrus, 1969). Thus, strategically implemented index selection of correlated yield and quality traits may be the best approach for melon improvement in such populations.

The varied growth habits of melon provide for a wide array of architectural plant types (Figure 1). The three primary architectural types recognized in melon include vining (Rosa, 1924), dwarf (syn. short-internode or bush) (Mohr and Knavel, 1966), and bird-nest (Paris *et al.*, 1981). These architectural types feature various combinations of vining habit (determinate or indeterminate), internode length (standard or shortened), and branch number (unilateral or multilateral).

In the 1970s and 1980s, both dwarf and bird-nest types were considered to have potential for increasing melon yield in once-over or mechanized harvesting operations (Paris *et al.*, 1981; Nerson *et al.*, 1983; Mohr and Knavel, 1966). Dwarf melon plant types were proposed as a means of increasing yield because their small-sized vines could be planted at higher densities (e.g., in close row spacing with staggered double rows), and each dwarf plant would theoretically support a single fruit. It was believed that higher yield would be achieved by the increased number of plants and that fruit development would be synchronized across the field, thus making once-over or mechanical harvesting practical (Knavel, 1988, 1990, 1991). The initial breeding efforts of dwarf cultivars proved difficult and required over 10 years to complete (Mohr and Knavel, 1966; Davis *et al.*, 1976; Zink, 1978, 1980; Halsey, 1980). In the

United States, the breeding of dwarf melons (Mohr and Knavel, 1966; Davis *et al.*, 1976; Zink, 1978, 1980; Halsey, 1980) has not resulted in superior yielding cultivars, and their fruit are often rather small for commercial acceptance (Nerson and Paris, 1987). The deficiencies of the dwarf types are probably related to their relatively small total stem and leaf area, which affect net photosynthetic capacity and efficiency (Knavel, 1988, 1990).

Case study for plant improvement The case study presented below typifies breeding procedures for the introgression of exotic genes into elite melon germplasm, and genetic assessments used to define work plans for plant improvement. It models the

introgression of multiple lateral branching and fruit set for changed plant architecture, which is the result of a co-operative project between J.D. McCreight (USDA, ARS, Salinas, CA) and J.E. Staub (USDA, ARS, Madison, WI).

Initially, horticulturally unique germplasm designated CR was received from Mr. Claude Hope, Cartago, Costa Rica (Figure 2). This accession, *C. melo* ssp. *agrestis* (Naud.) Pangalo, is characterized by a “fractal” or radiant growth habit (Smith, 1984; Prusinkiewicz and Harlan, 1989). CR is early flowering, monoecious, fast growing, indeterminate, possesses standard size internodes, abundant branching (6–12 primary branches), and bears many small fruits (up to 100 fruits/plant), 3–6 cm in diameter (Zalapa

Figure 2 Fruit and vine characteristics of a monoecious fractal exotic melon (*Cucumis melo* L.) accession (CR-1) originating from Costa Rica (a and b) and an extreme fractal indeterminate monoecious line USDA 846-1 (c and d) derived from a cross between CR-1 and indeterminate andromonoecious cultivar Top Mark

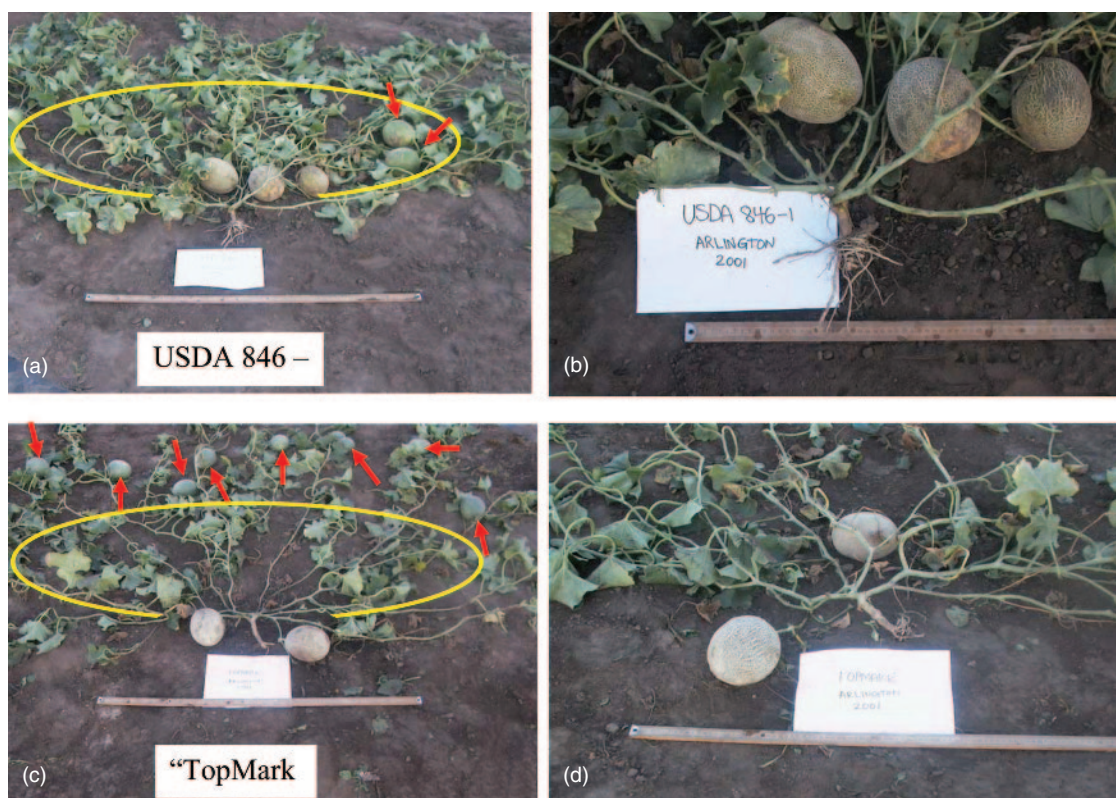

Figure 3 Vegetative growth habit, branching, and fruiting patterns in melon (*Cucumis melo* L.) lines USDA 846-1 (a and b) and cultivar Top Mark (c and d)

et al., 2006). The fractal architecture of CR is distinct from the vining, dwarf, and bird-nest plant habit, and its unique habit is a function of internode length (standard size) coupled with a comparatively high number of primary, secondary, and tertiary branches.

A monoecious, early flowering CR plant having 12 primary branches was selected in 1996, and was subsequently crossed to an F_1 plant derived from a cross between andro-monoecious USDA lines FMR#8 and SC#6. A monoecious, early flowering plant was then selected and self-pollinated four times to produce an inbred line designated USDA 846-1 (Figure 3). This monoecious, fractal, highly branched (5–8 primary branches) line produces a concentrated fruit set (2–5 fruits near the crown of the plant), and is capable of multiple fruiting cycles (Zalapa *et al.*, 2006).

USDA 846-1 (P1) was crossed to “Topmark” (P2), which is andro-monoecious, possesses between two to four lateral branches, and produces

a diffuse, distal fruit setting habit typical of commercial vining melon types (Figures 2 and 3). A single F_1 plant from this initial cross was self-pollinated to generate F_2 individuals, which were subsequently used to produce several BC1 and 119 F_3 families. A generation mean analysis was performed to estimate gene action, trait heritabilities, and least effective factors contributing to expression of yield components (Zalapa *et al.*, 2006). The F_3 families were assessed for variance of yield components (i.e., days to anthesis, primary branches number, fruit number and weight per plant, average weight per fruit, and days to fruit maturity (Zalapa *et al.*, 2007a), and subsequently used to develop recombinant inbred lines (RIL) for detection of QTLs controlling yield and quality component traits (Zalapa, 2004; Zalapa *et al.*, 2007b).

Generation mean and variance component analyses indicated that significant phenotypic variation existed in advanced families for

continued selection (Zalapa *et al.*, 2006, 2007a). Examination of the RILs in multiple environments (California and Wisconsin) detected location-independent QTLs that were distributed across nine linkage groups (Zalapa *et al.*, 2007b). Thirteen (43%) of these QTLs were detected consistently across locations. These results suggest that marker-assisted selection (MAS) will likely have utility in breeding programs directed toward improving yield through alterations in plant architecture.

Melon breeding has provided superior cultivars for improved human health. Historic achievements include the following: (1) development of pest-resistant germplasm through seedling screening and mature plant techniques; (2) uniform external characteristics (e.g., netting, ribbing, etc.); (3) improved internal characteristics (e.g., sweetness, carotenoid content, texture, etc.), and (4) characterization of sex types to produce primarily andro-monoecious commercial hybrids. With the advent of molecular tools, dissection of complex traits (disease, yield, quality, and abiotic stress) will allow for gene identification and manipulation through biotechnology (e.g., MAS and transgenic introgression). Such manipulation will likely provide more rapid release of unique disease resistant, high yielding genotypes that possess high fruit quality.

1.2.4.2 *Cucumber*

There are two basic cucumber types: those that are eaten fresh (i.e., fresh or slicing market types; Wehner and Horton, 1986) and those that are consumed as a processed product (processing or pickling types; Staub and Bacher, 1997). The major fruit types are the American processing and fresh market types, the Dutch gherkin and greenhouse types, the German Schalgurken type, the Mideast Beit Alpha type, and the Oriental trellis (burpless) type.

Fresh market types are field or greenhouse grown, and are usually between 15 cm (i.e., US and Mediterranean) to 40 cm (i.e., European) in length. Less common fresh market types include Sfran (compact fruit types marketed in the Persian Gulf) and “lemon” cucumber (shape similar to a lemon with pale, greenish-yellow skin; hermaphroditic). Processing types differ depending on cultural preferences (e.g., the United States vs. Europe).

Breeding objectives are determined by the requirements associated with cucumber market classes (e.g., US processing (pickling), US fresh market, European glasshouse, Mediterranean, Asian glasshouse). Breeding plans are driven by historically proven procedures and emerging technologies. Typically, breeding follows a series of steps that consist of population development and improvement, line extraction, and hybrid evaluation. Population development via recurrent selection (e.g., yield and quality components), pedigree selection (e.g., disease resistance), and backcross introgression (e.g., sex expression) are characteristic of most cucumber breeding programs. The breeding process results in the refinement of populations derived from intercrossing elite and/or exotic (unadapted) germplasm, the development of inbred lines from such populations, and the identification of commercially acceptable F₁ hybrids.

Early genetic enhancement of cucumber (1850–1980) focused mainly on the incorporation of disease resistance and changes in plant architecture (e.g., sex expression, growth habit) that were augmented by improved cultural practices (Lower and Edwards, 1986; Tatlioglu, 1993; Staub and Bacher, 1997). The genetic control for resistance to scab (*Ccu*), downy mildew (*dm*), bacterial wilt (*Bw*), angular leaf spot (*psl*), anthracnose (*Ar*, *cla*), target leaf spot (*Cca*), *Corynespora* leaf spot, and *Fusarium* (*Foc*) is conditioned by few genes (Robinson *et al.*, 1976; Pierce and Wehner, 1990). Seedling cotyledon tests have been developed to screen for resistance to the pathogens of each of these diseases allowing for the release of a wide array of resistant cucumber market types (Lower and Edwards, 1986). Seedling screening procedures are amenable to simple backcrossing and selfing strategies for line development. In contrast, the genetics of resistance to viruses, such as CMV (*Cmv*), WMV (*Wmv*), Potyvirus, and ZYMV (*zymv*), or to powdery mildew (*pm-1*, *-2*, *-3*, *pm-h*), green mottle mosaic virus (GMMV), gummy stem blight, belly rot, cottony leak, *Phytophthora* rot, and gray mold is complex. Thus, breeding for resistance to these diseases, as well as many architectural traits, requires exacting test protocols (often in the mature plant stage) and extensive replicated testing (field and greenhouse) in multiple environments.

Yield and quality are a major focus of cucumber improvement and consist of many extensively reviewed, interrelated traits that are often the focus of the cucumber breeder (Lower and Edwards, 1986; Tatlioglu, 1993; Lebeda *et al.*, 2006). These quantitatively and qualitatively inherited traits range from disease resistance to plant and fruit architecture and habit. Conventional breeding for yield involves selection for total yield or index selection for yield components, and can be enhanced by MAS (Fazio *et al.*, 2003a; Fan *et al.*, 2006). Correlations among traits are important when manipulating plant architecture for yield improvement, since source-sink relationships impose practical constraints on fruit development. Correlations between and among yield and quality component traits have been investigated, and this information is used during recurrent selection procedures. Typical fruit quality traits considered for selection are fruit size, external and internal quality, and for US processing cucumbers, characteristics associated with processing methods. Common traits selected for yield improvement include fruit number and weight, sex expression, days to anthesis, lateral branch number, and fruit length and diameter.

Case study for plant improvement *C. hystrix* Chakr. ($2n = 2x = 24$) has been collected only in the Yunnan province of China (Chen and Adelberg, 2000; Chen and Kirkbride, 2000). It is sparingly sexually compatible with *C. sativus*, and harbors some degree of resistance to CMV and ZYMV and comparatively strong resistance to PRV (Chen *et al.*, 1997a, b, 2004). In addition, it possesses root-knot nematode resistance (Chen and Lewis, 2000; Chen *et al.*, 2001), gummy stem blight resistance, downy mildew resistance, unique nutritional qualities, and tolerance to growth under low irradiance and temperature not known in *C. sativus* (Chen *et al.*, 2004).

Fertile, interspecific hybrid progeny ($2n = 19$, with 12 and 7 chromosomes contributed by *C. hystrix* (H) and *C. s. var. sativus* (S), respectively) have been obtained through F_1 embryo rescue by Jin-Feng Chen (Nanjing Agricultural University, Nanjing, China; Chen and Staub, 1997; Chen *et al.*, 2002) (Figure 4). Subsequently, an amphidiploid (HHCC, $2n = 4x = 38$)

was produced via chromosome doubling, and was designated as a new synthetic species, *C. hystivus* Chen (Chen *et al.*, 2003). Partially fertile allotriploids ($2n = 3x = 26$; HSS), fertile diploids ($2n = 2x = 14$; SS), and partially fertile monosomics ($2n = 15$; SS + 1H) have also been derived from *C. hystivus* \times *C. s. var. sativus* crosses (Chen *et al.*, 2004; Chun-Tao *et al.*, 2005). These experiments demonstrate the unique introgression of exotic germplasm into elite cucumber germplasm.

The “proof of concept” for use of *C. hystrix* germplasm for cucumber improvement has been made (i.e., fruit with acceptable quality; Figure 4). However, during backcrossing many of the unique qualities of *C. hystrix* have likely been lost (e.g., pest resistance). The introgression of such traits will require rigorous selection of backcross families for economically important traits.

Historic cucumber breeding achievements include the following: (1) development and use of disease screening technologies to develop resistant cultivars; (2) identification of biochemical pathways, which regulate sex expression; (3) development and implementation of controlled pollination procedures, and (4) characterization of genetics, which stabilize gynoeious sex expression (Lower and Edwards, 1986). More recently, the development of sophisticated breeding strategies, the creation of sophisticated computer algorithms, and the development of molecular marker technologies has allowed for an in-depth quantification of some economically important metric traits, the development of unique genetic stocks, and an improved understanding of the cucumber genome (Serquen *et al.*, 1997; Fazio *et al.*, 2003b). Future contributions may include the introgression of exotic genes for improved disease resistance, yield, and improved human health (Figures 4 and 5).

1.2.5 Limitations of conventional breeding and application of biotechnology

Genetic improvement of both melon and cucumber (most particularly cucumber) has been impeded by their narrow genetic base (3–8% (cucumber) and 15–20% (melon) on a per band basis). As molecular marker technologies become more efficient, effective, and affordable, they will be increasingly used to augment

Figure 4 Fruit and vegetative habits of *Cucumis hystrix* (Chakr.) (a; $2n = 2x = 24$), a BC_3S_1 line derived from a cross between *C. hystrix* and *C. sativus* L. ($2n = 2x = 14$) (b; $2n = 2x = 38$), an F_1 derived from a cross between the BC_3S_1 and an elite *C. sativus* line (c), and vine biomass differences between the $BC_3S_1 \times C. sativus$ line (d; left is the F_1 and right is the standard indeterminate *C. sativus* commercial hybrid)

and enhance conventional phenotypic selection during population development and/or inbred line development.

1.2.5.1 Application of marker-assisted selection

Melon The genome size of melon has been estimated to be $4.5\text{--}5.0 \times 10^8$ bp, about three times that of *Arabidopsis* (1500–2000 cM; Arumuganathan and Earle, 1991). Genetic analysis of melon has led to the description of roughly 200 major genes that control morphological traits (Pitrat *et al.*, 2000). However, only a few of these genes have been assigned to linkage groups.

Molecular markers (e.g., amplified fragment length polymorphism, cleaved amplified polymorphic sequences, inter-simple sequence repeat,

random amplified polymorphic DNA, restriction fragment length polymorphism, sequence characterized amplified region, single nucleotide polymorphism, and simple sequence repeat) have been used to identify and map disease and pest resistance genes in melon. Several moderately saturated genetic maps have been developed using various molecular markers (RAPD, RFLP, and SSR) (Danin-Poleg *et al.*, 2002; Périn *et al.*, 2002b; Gonzalo *et al.*, 2005). Genes of economic importance that have been mapped include those for disease resistance (e.g., *Fom-1*, *Fom-2*, *Nsv*, *Pm*, *Pvr*, *CMV*, and *Vat*), flowering characters (e.g., *a* and *ms*), plant architecture (e.g., *si* and *lmi*), and ethylene production during fruit maturation (e.g., *CM-aco1*) (Dogimont *et al.*, 2000; Périn *et al.*, 2002a; Pitrat *et al.*, 2000). More specifically, marker-trait associations have been identified for *Fusarium* wilt (*Fom-1* and *Fom-2*; Wechter *et al.*,

Figure 5 A high carotene (vitamin A) cucumber line (*Cucumis sativus*) line derived from a cross between an exotic *C. sativus* accession originating from China and an elite USDA US processing cucumber line

1995, 1998; Wang *et al.*, 1998, 2000; Zheng *et al.*, 1999; Karsies *et al.*, 2000; Zheng and Wolff, 2000; Garcia-Mas *et al.*, 2001; Brotman *et al.*, 2004), ZYMV (Zym 2 and Zym 3; Danin-Poleg *et al.*, 2002), PRSV (Prv; Garcia-Mas *et al.*, 2001; Brotman *et al.*, 2002, 2004), virus aphid transmission resistance (Var; Brotman *et al.*, 2002), powdery mildew (Pm; Fukino *et al.*, 2002), and melon necrotic spot virus (Nsv; Garcia-Mas *et al.*, 2004; Morales *et al.*, 2004). Additionally, the map positions of complex traits contributing to fruit quality (Périn *et al.*, 2002b; Monforte *et al.*, 2004) and yield (Zalapa *et al.*, 2006) controlled by QTL have been determined. This information provides

opportunities for increasing breeding efficiency and effectiveness through MAS.

Cucumber Cucumber possesses a rather small genome size (~880 Mbp (mega base pair), 750–1000 cM; Staub and Meglic, 1993), low chromosome number, and has a rapid life cycle (three cycles per year). In addition, fairly saturated genetic linkage maps have been developed, and QTL analyses have identified several genomic locations involved with important traits (Serquen *et al.*, 1997; Fazio *et al.*, 2003b).

The pyramiding of simply inherited genes (e.g., disease resistance) during germplasm enhancement is common, and has proven useful in the improvement of many crop species. In cucumber, the pyramiding of disease resistance genes resulted in important inbred lines and populations. MAS has potential for augmenting conventional breeding programs to increase breeding efficiency and effectiveness during pyramiding selection. MAS can be applied to the improvement of cucumber and melon if marker-trait associations are robust and stable. This has, in fact, been the case with cucumber where MAS has proven effective in selection for yield component traits during backcross introgression (Fazio *et al.*, 2003a; Fan *et al.*, 2006).

1.2.5.2 Application of transgenic technologies

New melon and cucumber varieties have been traditionally released by conventional breeding. With the exception of *C. hystrix* introgression, transfer of target traits has been limited within many cucurbit species. The development of plant regeneration techniques and gene transfer via particle bombardment and gene specific *in vitro* transfer (transformation) provide opportunities for augmenting conventional breeding strategies (Fang and Grumet, 1990, 1993; Ezura *et al.*, 2000). For instance, ethylene promotes climacteric melon fruit ripening and genes that encode ripening operate to modulate the ethylene synthesis pathway, 1-aminocyclopropane-1-carboxylate synthase oxidase. “Knocking out” such genes by antisense can result in reductions in ethylene production (Ayub *et al.*, 1996) and thus could potentially increase fruit self-life (Bauchot *et al.*, 1998; Silva *et al.*, 2004). Disease resistance has also been introduced through transgenic techniques. Fang and Grumet (1993) have introduced resistance to ZYMV infection in melon. Yoshioka *et al.* (1992, 1993) have introduced genes conferring CMV resistance into melons. One group has been able to introduce genes conferring resistance to ZYMV, WMV2, and CMV, PRSV, and squash mosaic virus (SqMV) into melon and cucumber (Fuchs *et al.*, 1997; Tricoli *et al.*, 2002). All of these workers have achieved their results through

the transformation using constructs containing the coat protein genes of the target viruses. They indicate that transgenic technology could be used successfully in production agriculture, if negative socio-political barriers were to be removed, and if the significant regulatory hurdles to commercialization could be overcome. To date no transgenic melon or cucumber has been commercialized.

1.3 Watermelon

1.3.1 History, origin, and distribution

Watermelon was thought to have originated in southern Africa (Jeffrey, 2001) and has a long history of cultivation in Africa and the Middle East. Recently, however, several watermelon seeds that are 5000 years old have also been discovered in northern Africa (Wasylikowa and Van Der Veen, 2004). Therefore, southern or northern African origins are still unresolved. Nevertheless, it is commonly believed that watermelon originated from that continent and spread from there to the rest of the world. It spread to China and southern Russia by the 10th Century AD. By the 13th century, watermelon was grown in Europe and from there it was introduced to North America by the Spaniards in the 16th century, where it rapidly became popular with Native Americans (Jeffrey, 1975; Robinson and Decker-Walters, 1997). Watermelon grows in areas with temperatures warmer than 20 °C. Under suitable climatic conditions, its semi-tap root system can grow 2 m or more below the soil surface (Jeffrey, 2001). In the United States, watermelons are mainly grown in the southern and western states, such as Florida, Georgia, California, and Texas (Wehner and Maynard, 2003). Worldwide top watermelon-producers are listed in Table 1.

1.3.2 Botanical description: taxonomy, habit, habitat, genome size, and cytological features

Most cultivated or edible watermelons belong to the species *Citrullus lanatus*, which includes two morphological subspecies, *C. lanatus* subsp.

Table 1 Production of watermelon in 2005 and 1990^{(a)(b)}

Country	Area (ha)		Production (t)	
	2005	1990	2005	1990
China	2 014 500	574 045	69 315 000	10 955 371

^(b)The top 10 watermelon producing countries in 2005 are ranked according to total production in 2005; 1990 data are included for comparison

lanatus (Thunb.) Matsum. & Nakai (cultivated watermelon; although *Citrullus vulgaris* Schrad. is still found in the literature) and *C. lanatus* subsp. *vulgaris* Schrad (Jeffrey, 2001). The latter contains wild annual forms that today grow only in the Kalahari Desert in southern Africa and are known under the local name *tsamma*, which is considered the ancestor of cultivated watermelon (Jeffrey, 2001). This subspecies also contains other botanical varieties such as citron, which is a source of *Fusarium* wilt resistance in watermelon (Robinson and Decker-Walters, 1997).

Cultivated watermelon is an annual herb with long (up to 10 m) stems creeping on the ground, with curly tendrils at each node. Stems are thin, hairy, angular, and highly branched. Leaves are hairy and deeply palmate with 3–5 lobes, on long petioles (Jeffrey, 1978). Most watermelon plants produce separate male (staminate) and female (pistillate) flowers, which are easily distinguishable due to their watermelon-like ovary. This condition of monoecy is controlled by a single dominant gene (Poole and Grimball, 1945). Andro-monoecious plants are not as common and have both male and perfect flowers, the latter housing both male and female floral organs. The separation of the male and female flowers means that proper pollination has to be carried out by insects, mostly honeybees (Fehér, 1993). This is true even for perfect flowers. Male flowers also appear earlier than the female flowers in both monoecious

and andro-monoecious plants. However, most modern varieties are monoecious, which facilitates commercial seed production of inbred lines and hybrid varieties. The ratio of male and female flowers under field conditions varies from 4:1 to 15:1 and most varieties have a ratio of 7:1, although 4:1 is more desirable for higher yield (Fehér, 1993; Wehner *et al.*, 2001). Watermelon fruits are usually round or oval/ovate. Fruits can weigh from 2–20 kg. Fruit sizes are divided into five categories: icebox (<5 kg), small (5–8 kg), medium (8–11 kg), large (11–15 kg), and giant (>15 kg) (Wehner *et al.*, 2001). Seed color varies from black to white. Fruit rind color can vary from pale yellow to dark green, with or without stripes, and flesh color can be yellow, pink or red, rarely white (Jeffrey, 1978).

Watermelon is usually diploid and has 11 pairs of chromosomes ($2n = 22$, $x = 11$) (Fehér, 1993; Wehner *et al.*, 2001). Because of its small genome size (4.25×10^8 bp), similar to melon and cucumber (Arumuganathan and Earle, 1991), the chromosomes are small and stain poorly for cytological studies, although an improved staining procedure has been developed (Skorupska and Allgood, 1990). Different ploidy levels exist in cultivated watermelons but diploids (which may contain 0.5–1% polyploids), triploids, and tetraploids have been commercially important (Fehér, 1993). Tetraploids may produce smaller fruits than diploids, but their fruit quality is excellent and germination is typically better than their diploid counterparts. In addition, tetraploids are critical in producing triploid seedless watermelons.

1.3.3 Economic importance

Watermelon production was more than doubled from 34 million tons in 1991 to 77.5 million tons in 2001 (Taylor and Brant, 2002). Production in top countries producing watermelon in 2005 increased tremendously even though in some countries such as the United States, where production has increased by 56% since 1990, the growing area has remained relatively constant (Table 1). The United States produced 1 718 920 t of watermelon in 2005 with a market value of over US\$ 400 million (NASS, 2006). But this by no means reflects the total consumption, because there are significant

imports from other countries. For example, the United States imported 248 057 t of watermelon in 2004 (FAO, 2006).

Delicious as a dessert eaten raw, watermelon is a rich source of vitamin A, β -carotene/lycopene and potassium (Robinson and Decker-Walters, 1997; Holden *et al.*, 1999; Wehner and Maynard, 2003). Although known for its high lycopene content, tomato actually contains less lycopene than red-fleshed watermelon on fresh weight basis (Perkins-Veazie *et al.*, 2001). In fact, it has been reported that on average, watermelon contains 40% more lycopene than raw tomatoes (Arnold, 2002). Yellow-fleshed watermelon contains a little lycopene, a potent antioxidant and anticancer agent (Rao *et al.*, 2006) but has higher carotene (vitamin A) content (Wehner and Maynard, 2003). Watermelon juice can also be fermented into alcoholic beverages (Robinson and Decker-Walters, 1997). In addition to fruits, watermelon seeds yield an edible oil, and are consumed roasted.

1.3.4 Conventional breeding: breeding objectives, tools and strategies, and achievements

Objectives of most watermelon breeding programs have been yield, quality, and disease resistance. Over the past century, conventional breeding has tremendously improved earliness, plant architecture (dwarfness), fruit yield (larger fruit), quality (increased soluble solids/sugar and lycopene content), diversity (e.g., seeded and seedless), disease resistance (*Fusarium* wilt, anthracnose and viruses including WMV, cucumber green mottle virus, telfairia mosaic virus, alfalfa mosaic virus, and ZYMV), and shipping quality (resistance to cracking) (Fehér, 1993; Wehner *et al.*, 2001; Gusmini and Wehner, 2006). Improved resistance to diseases such as bacterial fruit blotch and gummy stem blight remains a challenge (Gusmini *et al.*, 2005). However, sources of resistance have been identified for all important diseases in watermelon (Fehér, 1993; Wehner *et al.*, 2001). It is possible through conventional breeding to integrate these resistance traits into a desirable horticultural background, especially for resistances controlled by single genes. Over 500 diploid cultivars were developed in the United States

during the last two centuries, but there is still an ongoing need to improve watermelon, particularly in disease resistance and quality (Levi *et al.*, 2001).

Conventional breeding usually involves crossing between elite varieties, or an elite variety with another line that has one or more desirable traits. These varieties/lines may be selected based on the breeding objectives. The crossing has to be performed in an enclosed or an isolated area to minimize pollen contamination by insects. Progeny from the crosses are subsequently evaluated and re-evaluated in a variety of environments according to the breeding objectives. It is therefore critical to develop practical evaluation (field, greenhouse, or laboratory) criteria and selection (pedigree, recurrent, or backcross) strategies. After years of testing and selection, the best performers are released as certified varieties. Genetic diversity is a key to meet the needs of the growers/consumers, because not all varieties are going to be high yielding and of good quality in all growing areas.

The method used for trait evaluation has to be rapid and robust, such that a large number of lines can be screened within a certain period of time. For example, evaluation of sugar (soluble solids) content can be based on taste and refractometer readings (Wehner *et al.*, 2001). Refractometer readings are easily made in the field using a hand-held unit, which provides data on percentage of soluble solids ($^{\circ}$ Brix). For a variety to be acceptable, its soluble solids content should be at least 10% ($^{\circ}$ Brix) although newer varieties can have higher value of 14% (Wehner *et al.*, 2001). High sugar content and sweetness are the critical factors in determining the quality of many cultivars of watermelon. However, there may also be need for low sugar but red-fleshed watermelons for people on a low-carbohydrate diet, or for people with diabetes (Pons, 2004).

There are several selection strategies used in conventional watermelon breeding: backcross, pedigree, and recurrent selections (Wehner *et al.*, 2001). Backcross selection is used to transfer a single-gene trait from a donor to an otherwise superior inbred recipient, which is the recurrent parent. It may take more than five generations of selection and backcrossing to recover the genotype of the recurrent parent and much longer if the trait is recessive. The use of genetic markers linked to the trait has proven to shorten the generation time. In pedigree selection, two or more adapted and

complementary parents are crossed to form the hybrid (F_1) generation, which is then self- or sib-pollinated to form a segregating (F_2) population. The F_2 is self- or sib-pollinated while selecting for highly heritable (qualitative) traits to form the F_3 generation. Selections in later generations should focus more on quantitative traits when the plants are more uniform. Single-seed-descent is a modified pedigree selection in which selection is not practiced until later generations when quantitative traits such as yield and earliness are selected. Recurrent selection is used for population improvement. For example, an elite population can be developed by intercrossing more than two selected genotypes and select for qualitative traits in early and quantitative traits in late generations.

Many varieties have been developed in the latter part of last century through conventional breeding (Wehner *et al.*, 2001): “Charleston Gray” (USDA, Charleston, 1954), “Crimson Sweet” (Kansas State University, 1963), “Calhoun Gray” (Louisiana State University, 1965), and “Dixielee” (1979), “Jubilee” (1963), and “Smokylee” (1971) (all from the University of Florida) have high resistance to *Fusarium* wilt. “Dixlee” (University of Florida, 1979) and “Sangria” F_1 (Novartis, 1985) have dark red flesh. “Millionaire” F_1 , 3x (Harris Moran, 1992) and “Royal Jubilee” F_1 (Seminis) have consistently high yields. “Crimson Sweet” (Kansas State University, 1963) and “Sugarlee” (University of Florida, 1981) have high soluble solids. “Kengarden” (University of Kentucky, 1975) has dwarf vines. “Tri-X-313” F_1 3x (Novartis, 1962) is seedless. “Minilee” (University of Florida, 1986), “Mickylee” (University of Florida, 1986), “New Hampshire Midget” (University of New Hampshire, 1951), “Sugar Baby” (M. Hardin, Oklahoma, 1955), and “Tiger Baby” (Seminis) are icebox size. “Yellow Doll” (Seminis, 1977) has canary yellow flesh. Commercially, the most popular seeded varieties have dark red flesh, blocky (elongated) shape, and weigh 8–11 kg while popular seedless fruits have to be oval shaped and medium sized (5–8 kg), in addition to being red flesh and sweet (Wehner and Maynard, 2003). Varieties with dark red flesh include “Dixielee”, “AU-Sweet Scarlet”, “Red-N-Sweet”, and “Sangria”.

Although most earlier varieties have been open-pollinated, almost all watermelon varieties used

in the United States are now diploid hybrids (Kapiel *et al.*, 2004). A survey of watermelon varieties found that hybrids and sweet varieties are popular with growers in the United States due to their wider adaptation and quality. Another reason is that hybrids can be used to combine traits inherited in a dominant fashion from the two parents, such as red or yellow flesh, resistance to *Fusarium* wilt and anthracnose, and resistance to powdery mildew because their parents can accumulate those traits through inbreeding (Robinson, 1999; Wehner *et al.*, 2001). Like corn, watermelon is monoecious; but unlike corn, it can undergo inbreeding indefinitely without inbreeding depression. Hybrids have provided increased profitability to growers. (Rhodes and Zhang, 2000).

Eating watermelon with seeds is apparently a nuisance, an important reason why seedless watermelons (Figure 6) are produced and becoming popular with consumers (Kapiel *et al.*, 2004). Although watermelon with empty seeds has been produced by pollination with pollen irradiated with soft x-ray (Sugiyama *et al.*, 2002), the most practical method to produce seedless watermelons is through triploid hybrids, which are produced by crossing a tetraploid female parent with a diploid male parent to produce a triploid (the reciprocal cross does not produce offspring, for reasons that are yet unclear). A tetraploid line with desirable traits has to be developed first from a diploid using a chromosome-doubling agent, such as colchicine (Zhang *et al.*, 1995). It takes extra time and effort to produce this tetraploid parent due to low fertility and frequent fruit abnormality. Triploid hybrids produced in such way are female sterile and fruits induced by pollination from viable pollen are therefore seedless. As a result, about one-third of the field has to be used for diploid plants to provide a pollen source. As in other hybrid production, the quality of the hybrid (triploid in this case) depends on the combinations of the parents. As with other hybrid seeds, production is now mostly done in developing countries, where the low cost of labor allows hand pollination to produce seeds for triploid watermelons to be economically viable (Kapiel *et al.*, 2004; Rhodes and Zhang, 2000).

Triploids have other advantages besides seedlessness. They are generally more resistant to many diseases for reasons mentioned above, have a fruit

Figure 6 An example of a seedless variety, Tri-X-Carousel: triploid seedless, oval, broad green stripes in light-green background [Reproduced with permission of Donald N. Maynard]

with a longer shelf life, with higher soluble solids than the mid-parent. Triploids also outyield their diploid parents (Kapiel *et al.*, 2004).

1.3.5 Limitations of conventional breeding and rationale for transgenic breeding

Conventional breeding has been very successful in exploiting genetic variability within the cultivated watermelon. However, the low genetic diversity among watermelon cultivars has generated the need to expand the genetic base of cultivated watermelon (Levi *et al.*, 2001; Gusmini and Wehner, 2005). Traits controlled by single genes, such as *Fusarium* wilt resistance, can be transferred to cultivated watermelon from wild relatives through backcross selection, a process expedited by MAS. This process still takes a long time and can be very expensive.

Another feature of watermelon breeding is the selection for seedless watermelon varieties, which have become popular in recent years. Generating tetraploids from diploid varieties by colchicine treatment is difficult, because the frequency of success is less than 5%, and is genotype dependent

(Rhodes and Zhang, 2000). This is in addition to the long process of selecting a tetraploid plant with decent fertility and fruit traits. To produce the triploid seeds, at least six skilled workers are needed for 3–4 weeks to pollinate 1 acre of a hybrid watermelon seed production field (Rhodes and Zhang, 2000). Triploid seeds also are difficult to germinate because of their thick and hard seed coat (Rhodes and Zhang, 2000; Kapiel *et al.*, 2004) although this can be improved by tumbling the seeds (Rhodes *et al.*, 1997).

Gene transfer through genetic transformation is not limited by species boundaries because no sexual cross is made. Traits are transferred through the introduction of specific genes, a process ultimately determined by the availability of genes of interest (not just traits of interest). Resistance to a particular disease can be introduced from wild species without long backcross selection. Furthermore, genes underlying any traits can be introduced into watermelon, thereby enhancing existing traits or creating new traits and increasing the genetic diversity. Genetic engineering overcomes hurdles of conventional breeding outlined above. However, its success ultimately depends

on consumer acceptance of genetically engineered food.

2. TISSUE CULTURE AND TRANSFORMATION OF CUCURBIT SPECIES

2.1 Plant Regeneration

The ability to regenerate whole plants from tissue explants or cell cultures is crucial to the development of any transformation protocol. Advances in tissue culture of cucurbits over the last 30 years laid the platform for transformation of the four major cultivated species of the Cucurbitaceae. Regeneration via embryogenesis and organogenesis has been reported for all the four cultivated species (Debeaujon and Branchard, 1993; Kathiravan *et al.*, 2006). However, despite the ability to manipulate cucurbits *in vitro*, regeneration and transformation of cucurbits remain challenging.

2.1.1 *Cucurbita pepo*

Nearly 40 years ago, Schroeder (1968) reported on embryogenesis in *C. pepo*. Embryos were observed forming from the pericarp wall of zucchini squash. Jelaska (1972, 1974) produced embryogenic callus from pumpkin by culturing hypocotyl sections on Murashige and Skoog (1962) medium (MS) supplemented with indole-3-butyric acid (IBA), indole-3-acetic acid (IAA), naphthaleneacetic acid (NAA) or 2,4-dichlorophenoxyacetic acid (2,4-D). Callus remained embryogenic for up to 15 years; and Juretic and Jelaska (1991) were able to regenerate whole plants from this callus. Squash plants have also been regenerated from shoot apices (Chee, 1991) and cotyledons (Chee, 1992) by culturing tissue on MS medium supplemented with 2,4-D or 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), 6-benzylaminopurine (BAP), and kinetin. Leljak and Jelaska (1995) induced somatic embryo formation on zygotic embryos without application of exogenous hormones by first wounding the zygotic embryos and then plating them on MS medium with NH_4Cl as the only source of nitrogen. Gonsalves *et al.* (1995) were able to regenerate squash from somatic embryos induced

on cotyledon of six squash cultivars including three zucchini hybrids, two yellow squash hybrids, and a Casserta inbred.

Regeneration of plants from inbred parental lines is important for the development of transgenic commercial hybrid lines. Tricoli *et al.* (1995) produced embryogenic callus from *in vitro* leaf explants from inbred parental lines of zucchini, yellow crookneck, and Lebanese squash by culturing leaf explants on MS medium supplemented with 1.2 mg l^{-1} 2,4,5-T and 0.4 mg l^{-1} BAP. Kintzios *et al.* (2002) showed that pretreating squash leaves with $186 \mu\text{M}$ kinetin for 48 h followed by transfer to hormone-free medium induced somatic embryo formation on leaf explants. More recently, advances have been made in regenerating *C. pepo* (Kathiravan *et al.*, 2006) and *C. maxima* (Lee *et al.*, 2003) through organogenesis. Adventitious shoots were produced from a very specific segment of the seedling existing at the junction between the cotyledon and hypocotyl (Ananthakrishnan *et al.*, 2003; Kathiravan *et al.*, 2006). Although the number of explants that produced shoots using this method reached 65%, the number of shoots produced per explant for most cultivars was low, ranging from 1.2 to 1.6 shoots per explant. To date, there are no published reports of transgenic squash plants being produced using organogenesis. The probability of transforming tissue capable of regeneration via organogenesis may be low given the highly specific location of the tissue capable of regenerating and the low number of shoots regenerating per explant.

2.1.2 *Cucumis melo*

Stimulation of *de novo* shoot formation from tissues harvested from *in vitro* grown seedlings is the principal method used to regenerate melons. Cotyledon (Moreno *et al.*, 1985; Dirks and van Buggenum, 1989; Niedz *et al.*, 1989; Roustan *et al.*, 1992; Adelberg *et al.*, 1994), hypocotyl (Kathal *et al.*, 1986), roots (Kathal *et al.*, 1994), callus (Bouabdallah and Branchard, 1986), and leaf (Kathal *et al.*, 1988; Dirks and van Buggenum, 1989; Chee, 1991; Yadav *et al.*, 1996) explants have been used for shoot regeneration. BAP in combination with IAA or NAA with or without the addition of abscisic acid (ABA) are the most

Figure 7 *Cucumis melo* regeneration from cotyledon explants. Organogenic callus developing from cotyledon explant (upper left), shoot-bud formation (upper right), shoot elongation (lower left), and root formation (lower right)

common plant growth regulators used to stimulate organogenesis, especially when cotyledon tissue is employed (Figure 7). Regeneration is also observed when BAP is replaced with kinetin or 6- γ,γ -dimethylallylaminopurine (2ip). However, regeneration frequencies are often reduced (Kathal *et al.*, 1988). Shetty *et al.* (1992) found that when added to the regeneration medium, 10 mM proline enhances shoot regeneration and salicylic acid at 50–200 μ M stimulates BAP-induced shoot regeneration. For cotyledon-based regeneration, most reports use cotyledons from *in vitro*-germinated seedlings that are younger than 4 days old, with the peak regeneration response seen on cotyledons 1–3 day(s) after germination (Tahar and De Both, 1989). Guis *et al.* (2000) regenerated plants from leaf explants using a combination of BAP and 2ip. Regeneration through somatic embryogenesis has also been achieved in melon. Somatic embryos can be produced from various explant tissues on medium containing 2,4-D, with or without NAA, in combination with

BAP or thidiazuron (TDZ). Somatic embryos have been produced from cotyledons (Oridate and Oosawa, 1986; Trulson and Shahin, 1986; Branchard and Chateau, 1988; Gray *et al.*, 1993; Guis *et al.*, 1997; Kintzios and Taravira, 1997), hypocotyls (Blackmon and Reynolds, 1982), hypocotyl-cotyledon border (Homma *et al.*, 1991), petioles (Tabei *et al.*, 1991), mature seed and cell suspensions (Oridate and Oosawa, 1986), and protoplasts (Moreno *et al.*, 1985; Debeaujon and Branchard, 1992). Nakagawa *et al.* (2001) found that addition of 0.5 μ M ABA enhanced somatic embryogenesis from cotyledon explants. They also observed that the addition of 150 mM mannitol in combination with 100 mM sucrose or 50 mM mannitol in combination with 200 mM sucrose increased embryo formation compared to 200 mM sucrose alone, possibly by inducing osmotic stress.

Development of somatic embryos into plants with normal morphology can be problematic. Kageyama *et al.* (1991) showed that washing cultures in medium containing 0.5% activated charcoal resulted in the production of greater numbers of normal somatic embryos. Despite substantial research, melon regeneration remains genotype dependent (Oridate *et al.*, 1992; Ficcadenti and Rotino, 1995; Molina and Nuez, 1995). Galperin *et al.* (2003) screened 30 melon genotypes for regeneration capacity and for 24 of these lines no normal shoot regeneration was observed. They identified a line with enhanced transformation regeneration capacity which they designated BU-21/3.

2.1.3 *Cucumis sativus*

Somatic embryos have been produced from leaves (Malepszy *et al.*, 1982; Malepszy and Nadolowska-Orczyk, 1983), cotyledon (Wyszogrodzka and Shahin, 1985; Trulson and Shahin, 1986; Cade *et al.*, 1988; Chee, 1990a), cell suspensions (Chee and Tricoli, 1988; Bergervoet *et al.*, 1989), hypocotyls (Rajasekaran *et al.*, 1983; Chee, 1990a), and protoplasts (Orczyk and Malepszy, 1985; Jia *et al.*, 1986; Colijn-Hooymans *et al.*, 1988; Punja *et al.*, 1990b). Malepszy *et al.* (1982) and Malepszy and Nadolowska-Orczyk (1983) produced embryogenic callus from leaf tissue in

cucumber using 2,4-D or 2,4,5-T in combination with BAP. Punja *et al.* (1990a) regenerated cucumber plants through both organogenesis and embryogenesis using petiole, cotyledon, and leaf tissue. Somatic embryos developed most prevalently on 2,4-D and BAP whereas NAA and BAP or NAA and zeatin resulted in the production of both somatic embryos and organogenic shoots. Preculturing the tissue in the dark was essential for achieving high frequency regeneration. Chee and Tricoli (1988) generated embryogenic cell suspensions from callus produced from leaf explants cultured on 1.2 mg l^{-1} 2,4,5-T and 0.8 mg l^{-1} BAP. The callus was produced on agar-solidified plates and transferred to liquid media of the same formulation to establish a suspension culture. The suspensions were subcultured every 7–14 days and periodically filtered through a 520-micron stainless steel screen to maintain a fine suspension. Washing cells once in MS basal medium with 0.5% charcoal, and twice in MS basal medium enhanced differentiation of embryos into plants. Plating cells and embryos on MS medium with 5% sucrose also enhanced embryo development. Lou *et al.* (1996) found that sucrose concentration influenced the morphogenic response in cotyledon explants. Sucrose levels of 131 mM induced adventitious shoot formation, 263 mM sucrose induced both adventitious shoots and embryos, and 394 mM sucrose produced only somatic embryos.

Regeneration of cucumber through organogenesis has been achieved from leaves (Seo *et al.*, 2000), hypocotyls (Selvaraj *et al.*, 2006), cell suspensions (Bergervoet *et al.*, 1989), and cotyledons (Wehner and Locy, 1981; Kim *et al.*, 1988). Kim *et al.* (2000) developed a high frequency shoot regeneration system from hypocotyls harvested 2 mm below the cotyledonary node of 3–5 days old seedlings cultured on 2.0 mg l^{-1} zeatin. Selvaraj *et al.* (2006) regenerated cucumbers from nodular callus induced from hypocotyl explants on 2,4-D and BAP. Cheng and Chen (2005) found that the addition of polyamines to the medium enhanced adventitious shoot formation from cotyledon explants.

2.1.4 *Citrullus lanatus*

Blackmon and Reynolds (1982) described shoot regeneration from half-cotyledons of “Charleston

Gray 133” using BAP or 2ip. Srivastava *et al.* (1989) regenerated plants from cotyledon and, to a lesser extent from hypocotyls, cultured on MS medium containing BAP. Krug *et al.* (2005) found that cotyledons harvested from 3-day-old seedlings were more responsive than cotyledons harvested from 1–5 day(s) old seedlings. Dong and Jia (1991) were able to regenerate plants from eight watermelon cultivars on MS medium supplemented with 5 mg l^{-1} BAP and 0.5 mg l^{-1} IAA. They found that regeneration potential dropped significantly in cotyledons from seedlings older than 7 days. Compton and Gray (1993a, 1994) extended this work to triploid and tetraploid watermelon. Compton (1999) found that germinating seeds in the dark improved organogenesis from excised cotyledons. For difficult genotypes, enhanced regeneration was obtained from explants that consisted of the whole cotyledon base (Compton, 2000). Somatic embryogenesis has been obtained in watermelon from immature cotyledons but the number of embryos produced per responding explant was relatively low (Compton and Gray, 1993b).

2.2 Plant Transformation

2.2.1 *Cucurbita pepo*

The only published accounts of transformation of *C. pepo* are in patents (Chee, 1997; Tricoli *et al.*, 2002). Chee (1997) describes both *Agrobacterium* and microprojectile-mediated transformation and uses either shoot tips or freshly cut mature seeds. Shoot apices consisted of the apical domes and some supporting tissues removed from young squash seedlings or from cotyledons. Alternatively, tissue from mature seeds was used. Tissue was submerged briefly in an overnight culture of C58 Z707 (Hepburn *et al.*, 1985), blotted dry, and co-cultured abaxial side down on MS medium supplemented with 1.2 mg l^{-1} 2,4,5-T, 0.8 mg l^{-1} BAP, and 0.1 mg l^{-1} kinetin or 5 mg l^{-1} 2,4-D. After 4 days, the tissue was transferred to fresh plates containing the same media formulation supplemented with 500 mg l^{-1} carbenicillin and $100\text{--}200 \text{ mg l}^{-1}$ kanamycin. After 9 weeks, developing transgenic callus was transferred to MS medium supplemented with 0.05 mg l^{-1} NAA and 0.05 mg l^{-1} kinetin, 500 mg l^{-1} carbenicillin, and

100–200 mg l⁻¹ kanamycin. As soon as plantlets developed, the apical region was excised and transferred to half-strength MS basal medium to induce root development. Microprojectile-mediated transformation utilized somatic embryos that were subjected to bombardment with DNA-coated beads. After bombardment, the tissue was transferred to nonselective media for 2 days and then transferred to selection media containing 100–200 mg l⁻¹ kanamycin.

In the protocol used to create the virus-resistant transgenic squash lines ZW-20 and CZW-3 (Quemada and Tricoli, 1992, 1995) commercialized by Asgrow Seed Company (Tricoli *et al.*, 2002), the seed coats were removed and the seeds were surface-sterilized for 20–25 min in 20% solution of sodium hypochlorite containing Tween 20 (200 µl per 1000 ml). Disinfection was followed by three rinses in sterile distilled water (100 ml per rinse). Seeds were germinated in 150 × 25 mm culture tubes containing 20 ml of one-fourth strength MS medium solidified with 0.8% Difco Bacto Agar. After 57 days cotyledons were removed from the seedlings, and the shoot tips were excised and transferred to GA7 vessels (Magenta Corp.) containing 75 ml MS medium solidified with 1.5% Difco Bacto Agar. Cultures were incubated in a growth room at 25 °C, with a photoperiod of 16 h of light. Light was provided with both cool fluorescent (Phillips F40CW) and plant growth (General Electric F40-PF) lamps. Leaf pieces (0.5 cm) were collected from *in vitro*-grown plants and soaked in *A. tumefaciens* broth culture (OD₆₀₀ 0.1–0.2) and transferred to 100 × 20 mm petri dishes containing 40 ml of MS medium supplemented with 1.2 mg l⁻¹ 2,4,5-T and 0.4 mg l⁻¹ BAP (MS-I) with 200 µM AS. Plates were incubated at 23 °C. After 2–3 days leaf pieces were transferred onto MS-I medium containing 500 mg l⁻¹ carbenicillin, 200 mg l⁻¹ cefotaxime, and 150 mg l⁻¹ kanamycin sulfate (MS-IA). After 10 days, leaves were transferred to fresh MS-IA medium. Thereafter, tissue was transferred to fresh MS-IA medium every 3 weeks. After approximately 16–24 weeks, kanamycin-resistant embryogenic callus was harvested and transferred to roller tubes containing liquid MS minimal organics medium supplemented with 500 mg l⁻¹ carbenicillin and 150 mg l⁻¹ kanamycin sulfate and 1.0 mg l⁻¹ CaCl₂ · 2H₂O. Developing embryos were harvested and transferred to MS

minimal organics medium containing 20 mg l⁻¹ AgNO₃. Germinating embryos were subcultured to fresh medium until rooted shoots were obtained. Plantlets were transferred to soil for R₁ seed production.

Published accounts only describe selection of transgenic squash using kanamycin selection. At 150 mg l⁻¹, kanamycin provides effective selection of transgenic callus from leaf explants, and nontransgenic plants that escape selection are extremely rare.

2.2.2 *Cucumis melo*

Despite significant research in the production of transgenic melons, reliable high-throughput production of phenotypically normal transgenic melons remains challenging for a variety of reasons, including the fact that transformation of melon remains highly genotype dependent (Gaba *et al.*, 2004). In addition, although regeneration potential is an important factor contributing to the ability to transform for a particular cultivar, high regeneration frequencies do not necessarily correlate with high transformation frequencies. Nearly 20 years ago, Tahar and De Both (1988) reported on the development of transgenic callus expressing the β -glucuronidase and neomycin phosphotransferase (*nptII*) genes. However, they were unable to regenerate plants. Tahar *et al.* (1989), Fang and Grumet (1990), Dong *et al.* (1991), Valles and Lasa (1994), and Curuk *et al.* (2005) produced fertile transgenic melon plants using *Agrobacterium*-mediated transformation of cotyledon explants with efficiency ranging from 3% to 7%. However, a large percentage of transgenic plants regenerated from cotyledon explants are tetraploid. Bordas *et al.* (1997) compared transformation frequencies using cotyledon versus leaf explants. They were able to produce transgenic melon plants from leaf explants at a frequency of 1.3%; lower than the 3% frequency they obtained from cotyledon explants. Guis *et al.* (2000) produced transgenic melons using leaf explants from 10-day-old seedlings, and in contrast to cotyledon explants, a large percentage of these plants were diploid. Ezura *et al.* (2000) showed that ethylene is produced by excised cotyledons and that production of this hormone is increased further by inoculation with

Agrobacterium. The addition of aminoethoxyvinylglycine (AVG), during co-cultivation increases the frequency of transient expression, suggesting that transformation efficiencies in melon may be increased by inhibiting ethylene production. Curuk *et al.* (2005) found that wounding cotyledon explants by vortexing with carborundum prior to inoculation with *A. tumefaciens* was important for transforming recalcitrant melon cultivars. The strain of *Agrobacterium* can also affect melon transformation efficiency. Based on β -glucuronidase (GUS) expression, Guis *et al.* (1998) were able to produce twofold higher transformation frequency using *Agrobacterium* strain C58 compared to LBA4404. One drawback of using C58 in melon transformation is that counter selection against strain C58 is less effective than against LBA4404, and cultures can often be lost through *Agrobacterium* overgrowth, which can sometimes manifest itself several months after counter selection has been initiated.

Although organogenesis has mainly been used for production of transgenic melon, somatic embryos have also been generated. Oridate *et al.* (1992) examined somatic embryogenesis in 18 melon cultivars and found significant differences in their embryogenic potential. Akasaka-Kennedy *et al.* (2004) produced transgenic melon plants via embryogenesis by pretreating cotyledon explants in liquid MS medium supplemented with 3% sucrose, 1.0 mg l^{-1} 2,4-D, and 0.1 mg l^{-1} BA (EI) for 2 days followed by inoculation with *Agrobacterium*. Explants were then transferred to agar-solidified medium for 4 days in the dark at 25°C . After co-cultivation the tissue was returned to liquid EI medium containing 25 mg l^{-1} kanamycin and 375 mg l^{-1} augmentin. Kanamycin-resistant callus was harvested and transferred to MS medium without growth regulators and supplemented with 50 mg l^{-1} kanamycin. Using this procedure, three transgenic plants were produced from 130 explants.

Historically, the *nptII* gene, which confers resistance to the antibiotic kanamycin, has been preferentially used for melon transformation. However, kanamycin often allows nontransgenic plants to escape selection (Fang and Grumet 1990; Dong *et al.*, 1991). Kanamycin levels ranging from 150 to 750 mg l^{-1} have been used. However, even at elevated kanamycin concentrations, non-

transgenic shoots are often recovered. Recently, Nunez-Palencia *et al.* (2006) used the selectable glyphosate resistance marker gene *CP4*, encoding the enzyme 5-enolpyruvylshikimate-3-phosphate synthase (EPSPS) and were able to produce two diploid transgenic melon events. However, they also experienced problems with the production of "escape" plants when selecting with $50 \mu\text{M}$ glyphosate.

Most reports of melon transformation involve the use of *Agrobacterium*. However, using microprojectile bombardment of 3–4 day-old cotyledon explants, Gonsalves *et al.* (1994) were able to achieve transformation frequencies comparable to *Agrobacterium*-mediated transformation in the production of transgenic *C. melo* cv. Topmark containing the coat protein gene of CMV.

Transformation of multiple genes into melon has been achieved. Tricoli *et al.* (2002) produced transgenic melons containing the seven transgenes including the CMV, PRSV, ZYMV, WMV2, SQMV21, SQMV41 coat protein genes, and the *nptII* gene. Seventy-five percent (27/36) of the transgenic melon lines produced using this construct contained all six coat protein genes (Tricoli *et al.*, 2002).

2.2.3 *Cucumis sativus*

Transformation of most of the major types of cucumbers has been achieved, including pickling, slicing, beet alpha, and greenhouse cucumber types. Plants have been transformed using *Agrobacterium rhizogenes* (Trulson *et al.*, 1986), *A. tumefaciens* (Chee, 1990b; Sarmiento *et al.*, 1992; Nishibayashi *et al.*, 1996; Tabei *et al.*, 1998; Tricoli *et al.*, 2002; Rajagopalan and Perl-Treves, 2005; He *et al.*, 2006), and microprojectile bombardment (Chee and Slightom, 1992). Trulson *et al.* (1986) were the first to report on transformation of cucumber. They inoculated hypocotyl sections with *A. rhizogenes* carrying the *nptII* selectable marker gene. Root development occurred on medium without exogenous hormones and by transferring roots to embryo-induction medium, a low percentage of embryos were produced. Transformed cucumbers have been produced using *A. tumefaciens*-mediated transformation of cotyledons (Chee, 1990b; Chee and Slightom, 1991; Tabei *et al.*, 1998), hypocotyls (Nishibayashi *et al.*, 1996) as

well as leaf and petiole tissue (Sarmiento *et al.*, 1992). Rajagopalan and Perl-Treves (2005) demonstrated that the way in which the cotyledon explant is dissected has a significant impact on transformation efficiency. Dissecting the proximal half of the cotyledon using a “V” shaped cut increased transformation efficiencies possibly due to increased exposure of meristematic cells to infection by *Agrobacterium*. Vasudevan *et al.* (2002) found transformation efficiencies in cucumber to be 2–3 times higher with *Agrobacterium* strain EHA105 compared to LBA4404. Chee and Slightom (1992) produced transgenic cucumber via microprojectile bombardment of embryogenic callus followed by regeneration of transgenic plants.

Kanamycin selection has been the most common plant selectable marker gene used for cucumber transformation. Sarmiento *et al.* (1992) found that 91% of the shoots produced from callus generated on 75 mg l^{-1} kanamycin were transgenic. Rajagopalan and Perl-Treves (2005) found that a step-wise increase in the level of kanamycin selection from 100 to 150 and finally to 200 mg l^{-1} reduced the number of false positive, and chimeric shoots regenerated from cotyledon explants. Tabei *et al.* (1994) compared hygromycin and geneticin to kanamycin selection and found that hygromycin selection, especially when used in liquid medium, was highly effective for the selection of transgenic cucumber. Nishibayashi *et al.* (1996) produced transgenic cucumber plants from callus derived from hypocotyl explants cultured on medium containing hygromycin B at 20 mg l^{-1} . Vengadesan *et al.* (2005) regenerated transgenic shoots from cotyledon explants using phosphinothricin (pmi) selection at $2\text{--}6 \text{ mg l}^{-1}$. Recently He *et al.* (2006) generated transgenic cucumbers shoots and plants with mannose selection using 10 g l^{-1} mannose and 10 g l^{-1} sucrose.

2.2.4 *Citrullus lanatus*

Choi *et al.* (1994) reported on *Agrobacterium*-mediated transformation of watermelon from cotyledon explants inoculated with LBA4404 carrying the *GUS* gene and the *nptII* gene, the latter being the most common selective agent used in watermelon transformation (Choi *et al.*, 1994; Tricoli *et al.*, 2002). However, Reed *et al.* (2001) were able to produce transgenic plants using the

pmi selection system and found that preculturing cotyledons on medium containing BAP for 5 days increases the competence of cells to be transformed. Ellul *et al.* (2003) produced transgenic plants from cotyledon explants containing the *Saccharomyces cerevisiae HAL1* gene and these plants exhibited enhanced salt tolerance. Park *et al.* (2005) transformed *C. lanatus* cv. Gongdae, a wild watermelon commonly used as rootstocks onto which commercial varieties of watermelon are grafted. Recently, Hema *et al.* (2004) used electroporation to introduce DNA into zygotic embryos and nodal buds of watermelon under both *in vitro* and *in vivo* conditions. They confirmed the presence of the *GUS* gene in progeny using Southern blot analysis, although complete Mendelian inheritance studies still need to be done in order to confirm stable integration. Chinese scientists have developed transformation procedures in watermelon that avoid the use of antibiotics by facilitating direct gene transfer by microinjection (Tao *et al.*, 1996; Chen *et al.*, 1998; Xiao *et al.*, 1999a, b, c). These and other approaches hold promise for the eventual incorporation of transgenic techniques into conventional breeding programs for plant improvement.

2.3 Regeneration of Whole Plants

2.3.1 *Cucurbita pepo*

Regeneration of whole squash plants from transgenic embryos can be labor intensive. Embryos produced and maintained for long periods on hormone media often are difficult to convert into whole plants. Even after the embryos begin to germinate, the developing plantlet can re-callus, become necrotic or vitrified, and fail to root. After establishment in soil, many transgenic squash plants exhibit a weak phenotype and often produce male flowers with poor pollen formation. These plants are however fully female fertile. Poor pollen set appears to be a byproduct of the long time the plant tissue spends *in vitro* under vigorous hormone treatment. To maintain the germplasm, transgenic female flowers can be pollinated with nontransgenic male pollen and seed set can be achieved. T_0 plants that produce healthy pollen can be self-pollinated or backcrossed to a nontransgenic inbred line and seed production is

normal. T₁ seed from self-pollinated plants or from plants in which the transgenic line serves as the female parent is often smaller than wild-type seed, but T₁ plants produced from these seeds exhibit normal phenotypes, are fully male fertile, and can be self-pollinated without lack of fertility. Seed set on T₁ plants is similar to nontransgenic lines.

2.3.2 *Cucumis melo*

Conversion of organogenic melon buds to shoots occurs at a high frequency, but vitrification of developing shoots can make shoot elongation and rooting problematic. However, the most significant problem associated with regeneration of melon is the occurrence of a high percentage of tetraploid plants (Ezura *et al.*, 1992; Guis *et al.*, 2000). These plants exhibit shortened internodes, increased stem girth, large flowers with deeper yellow pigment, larger pollen grains, and decreased pollen production. Fruits produced from tetraploid plants are flattened at the poles and bulge slightly at their equator. When self-pollinated, these plants produce poor seed set, typically 10% of their diploid counterpart. Successful hand pollination is difficult, and flowers often abort prior to fruit set. The application of lanolin paste containing BAP to the young ovaries at anthesis (Jones, 1965) can improve flower and fruit retention. The seed produced on polyploid plants, although viable, germinate poorly. Attempts to rescue this material via crossing pollen from tetraploid plants with diploid plants produce “hollow seed” that has seed coats but lack endosperm or an embryo (see discussion above on the production of seedless, triploid watermelon). The production of tetraploid plants is more prevalent when cotyledon tissue is employed. The ploidy level in the cotyledon may also be correlated with age. Guis *et al.* (1998) found that cotyledons from quiescent seeds contained mainly diploid cells, whereas cotyledons from 2-day-old seedlings contained 60% tetraploid cells. Tissue sources may increase the percentage of diploid plants. Curuk *et al.* (2003) regenerated shoots from hypocotyl explants from 4 days old seedlings of three melon cultivars, and 99% of the shoots were diploid. Guis *et al.* (2000) regenerated plants from leaf explants and recovered 85% diploid plants. The propensity for regenerating tetraploid plants appears to be independent of

melon type. For instance, inbred lines of western shipping melons can be identified that produce very few tetraploid plants while other cultivars produce a preponderance of tetraploid plants when regenerated from cotyledon explants.

2.3.3 *Cucumis sativus*

Conversion of cucumber somatic embryos into plants often requires further manipulation, including excision of the developing shoot tip from the embryo and transfer to fresh medium (Chee and Tricoli, 1988). Some developing embryos recallus and become impossible to convert into plantlets. As with other cucurbits, developing shoots can often display vitrification, making rooting and acclimatization to soil difficult. Colijn-Hooymans *et al.* (1994) found that the recovery of tetraploid plants increased with the age of the seedling when plants were regenerated through organogenesis from cotyledon tissue. The authors believed this phenomenon to be due to endoreduplication in the cells of the cotyledon prior to regeneration, as a result of a sudden increase in ploidy level in the cells of the cotyledons soon after germination. In contrast, plants produced via somatic embryogenesis from leaf tissue display a normal phenotype and readily produce seeds. Pollen production is normal and application of silver thiosulfate can be used to stimulate the production of male flowers, which can be used to self-pollinate the primary transgenic plant. Virus-resistant transgenic plants were regenerated through embryogenesis using leaf explants for pickling, slicing, and beet alpha type cucumbers and tested in field trials from 1989 through 2002 (ISB, 2007). These plants did not exhibit features indicative of polyploidy plants and other than their high level of virus resistance, appeared comparable to their nontransgenic counterparts in the field (D.M. Tricoli, unpublished data).

2.3.4 *Citrullus lanatus*

Transgenic plant recovery for watermelon can be compromised if cotyledon explants are maintained on medium containing cytokinin for an extended period. However, if cotyledons with developing buds are transferred to medium without plant

growth regulators, elongated shoots are produced. Once shoots reach 15 mm in size, they can be readily rooted on medium containing low levels ($1\text{ }\mu\text{M}$ IAA or $0.54\text{ }\mu\text{M}$ NAA) of auxin. Rooted plants are readily acclimated to soil (Compton *et al.*, 2004). Similar to *C. melo*, polyploid plants are commonly recovered from cotyledon explants of watermelon. Compton *et al.* (1996) found that 5–20% of shoots regenerated from diploid watermelon were tetraploid. In contrast to *C. melo*, tetraploid watermelons have commercial utility in the production of seedless triploids.

2.4 Testing for Activity and Stability of Inheritance of the Transgene; and Adverse Effects on Growth, Yield, and Quality

2.4.1 *Cucurbita pepo*

Tricoli *et al.* (1995) produced numerous transgenic squash lines containing viral coat protein resistance. A large percentage (over 80%) of these plants exhibited resistance to the virus from which the engineered coat protein gene was derived. Plants that were resistant in the T_1 generation remained

resistant in the subsequent generations. Most experimental lines were advanced through the T_2 – T_3 generation, exhibiting predicted Mendelian segregation and no evidence of gene instability. The deregulated lines ZW-20 and CZW-3 (Quemada and Tricoli, 1992, 1995) which were originally produced in yellow crookneck squash inbreds, were incorporated in breeding programs and backcrossed into many different squash types (yellow straightneck, green zucchini, casserta, English marrow, butternut, acorn, grey zucchini, and pumpkin) with no loss of efficacy (Tricoli *et al.*, 1995). Using embryo rescue, the alleles were also transferred from *C. pepo* to *C. moschata*, again with no loss of resistance. Nutritional composition of transgenic *C. pepo* remained unaltered (Quemada and Tricoli, 1992, 1995). Transgenic lines with single, double, and triple viral resistance were advanced to field trials and showed no adverse effects on yield or quality when grown under nonviral conditions and, as expected exhibited significantly greater yield and quality when grown under viral pressure (Fuchs and Gonsalves, 1995; Tricoli *et al.*, 1995; Fuchs *et al.*, 1998a, 1999; Figure 8). No difference was observed in time to flowering, fruit shape, susceptibility to powdery mildew, cucumber beetles, whiteflies, or

Figure 8 Asymptomatic transgenic squash segregant containing the CMV, WMV 2, and ZYMV coat protein genes (left) compared to a nontransgenic segregant (right)

aphids (Tricoli *et al.*, 1995). Percent emergence and days to flowering were similar for the transgenic and nontransgenic hybrids (Arce-Ochoa *et al.*, 1995). Nearly, all transgenic lines tested in the field exhibited normal plant architecture and growth. However, one line was observed in the field with increased bushy plant architecture. This trait appeared to be due to somaclonal variation and did not cosegregate with the transgene. The vast majority of transgenic squash lines produced exhibited a high level of virus resistance when the coat protein gene(s) were present in the hemizygous state, allowing virus-resistant hybrids to be readily produced. However squash line A127-1-2 transformed with the coat protein genes from SqMV mimicked the response of a single recessive gene (Provvidenti and Tricoli, 2002). Transgenic *C. pepo* has been in commercial production in the United States since 1995.

2.4.2 *Cucumis melo*

Field tests have been conducted with male sterile, long shelf life and virus-resistant transgenic lines (ISB, 2007). Field testing of virus-resistant transgenic melon lines showed no detrimental effects associated with the transgene. Nutritional analysis conducted on fruits harvested from transgenic and control lines showed no alteration in any of the nutritional components measured. However, in contrast to squash, high levels of virus resistance were only achieved in plants that were homozygous for the transgenes (Clough and Hamm, 1995; Fuchs *et al.*, 1997). Plants homozygous for the CMV, ZYMV, and WMV2 coat protein genes (designated CZW-30) never exhibited systemic symptoms of virus, and symptoms that did develop late in the season were the result of a single infection of one of the three viruses present in the field as opposed to mixed infections seen in the control lines. Hemizygous lines derived from CZW-30 developed systemic symptoms late in the season but still exhibited a 7.4-fold increase in fruit yields compared to control lines (Fuchs *et al.*, 1997).

2.4.3 *Cucumis sativus*

Field trials have been conducted on transgenic cucumbers engineered for viral resistance, herbicide

tolerance, and increased salt tolerance. Slightom *et al.* (1990) and Gonsalves *et al.* (1992) tested cucumber lines Poinsett 76 expressing the CMV coat protein gene for resistance to CMV. These plants were compared to nontransgenic Poinsett 76 and the traditionally bred CMV-resistant line, Marketmore. The level of CMV infection was determined at the end of the trial by enzyme-linked immunosorbent assay. The transgenic lines had significantly lower rates of infection than either Marketmore or nontransgenic Poinsett 76. Virus-resistant lines of pickling, slicing, and beet alpha types were tested for resistance to virus in the field using paired plot designs in which each transgenic line was paired with its nontransgenic counterpart. Transgenic lines containing the coat protein genes from CMV, ZYMV, WMV2, and the nuclear inclusion protein A and/or B from PRSV exhibited high field resistance against all four viruses, including PRSV (Tricoli *et al.*, 2002).

2.4.4 *Citrullus lanatus*

Field trials have been conducted on transgenic watermelons containing genes designed to confer parthenocarp and virus resistance (ISB, 2007). Virus-resistant lines containing the coat protein genes from ZYMV and WMV2 were mechanically inoculated with both viruses and displayed resistance to both ZYMV and WMV2 (Tricoli *et al.*, 2002). Control vines were highly symptomatic producing very few fruits and the fruits that were produced were very small in size.

2.5 Regulatory Status of Transgenic Cucurbits

Cucurbits are one of the few families of plants that thus far have examples of commercialized and commercially viable transgenic varieties. Two transgenic squash lines have been approved for commercial planting in the United States and have been reviewed for food safety in the United States and Canada. In the United States, the regulation of field trials is primarily the responsibility of the US Department of Agriculture's Animal and Plant Health Inspection Service (USDA-APHIS), and in some cases where plants are transformed with genes to confer pest and disease resistance and field trials exceed 10 acres, the Environmental

Protection Agency (EPA) as well. Food safety is assured by the consultation process established by the US Food and Drug Administration (FDA). In Canada, approval for use as food is granted by Health Canada.

The first transgenic line of *C. pepo* received deregulated status from the USDA-APHIS in 1994 (US Department of Agriculture, 1994), and has been on the market since 1995. This line was resistant to ZYMV and WMV2. A second transgenic line, resistant to CMV, ZYMV, and WMV2, received deregulated status 2 years later (US Department of Agriculture, 1996). Both lines also completed the US FDA consultation process (US Food and Drug Administration, 1995, 1997). Both lines of transgenic *C. pepo* were also approved for use as food in Canada (Health Canada, 1999a, b). Because the US EPA has jurisdiction over plants producing compounds that confer resistance to pests or disease, termed "Plant Incorporated Protectants" (PIPs), the virus coat proteins expressed in transgenic *C. pepo* also required an exemption from tolerance from that agency as well. A tolerance exemption for WMV2 and ZYMV coat proteins in one transgenic squash line was granted (US Environmental Protection Agency, 1994). The agency then granted a broader exemption for these coat proteins in or on all raw commodities in the United States (US Environmental Protection Agency, 1997a), along with similar broad exemptions for the coat proteins of CMV (US Environmental Protection Agency, 1997b) and PRSV (US Environmental Protection Agency, 1997c).

Because the squash hybrids developed from the two approved transgenic lines were not developed for Canadian conditions, only applications for food use have been applied for and granted in that country (Health Canada, 1999a, b). Therefore, while transgenic squash can be imported into Canada as a food product, it cannot be planted for production there. Elsewhere in the world, applications for regulatory approval of transgenic squash have not been submitted to any other regulatory agency. Therefore, import and planting of transgenic squash seed by other countries is not permitted without specific permits from those importing countries. International agreements covering the movement of genetically engineered organisms also apply to transgenic squash, as they would to other transgenic seeds or commodities.

Thus, the Cartagena Protocol on Biosafety, as well as other international agreements that have provisions that encompass transgenic crops, such as the International Plant Protection Convention, also cover the international movement of transgenic squash seed or squash fruit for human or animal consumption.

A detailed description of the safety data and evaluations of the two transgenic squash lines approved by US agencies has been published elsewhere (Quemada, 2002). Additional studies, while not submitted in connection with regulatory approvals, have further some potential risks posed by transgenic cucurbits. For example, Fuchs *et al.* (1998b) studied the potential for the coat proteins expressed in transgenic squash (and melons) to enable the transmission of nonaphid transmissible CMV. These studies showed that transgenic plants expressing coat proteins of aphid transmissible strains of CMV did not mediate the aphid transmission of nonaphid transmissible strains. Similar results were obtained in experiments involving transgenic squash plants expressing coat proteins of aphid transmissible ZYMV inoculated with nonaphid transmissible ZYMV strains (Fuchs *et al.*, 1998b). Further studies have shown that commercialized transgenic squash affect the pattern of the spread of virus infections in the field by preventing secondary plant-to-plant spread of viruses (Klas *et al.*, 2006).

3. FUTURE ROAD MAP

Previous sections in this chapter describe the considerable efforts spent by research groups in both public and private sectors to develop methods for insertion of genes into cucurbits via genetic engineering methods, and the limited examples of success in commercializing these plants. Nevertheless, the potential for significant contributions to the improvement of cucurbit crops via genetic engineering remains great. Whether this potential will be realized depends upon a number of factors. One important factor affecting the ability of the private and public sector, especially the latter, to develop further transgenic cucurbit varieties is the significant barrier presented by regulatory requirements that must be fulfilled before commercialization of these crops. The human effort and expense

required for regulatory compliance have resulted in an unfavorable cost/benefit picture for the development of transgenic varieties of small acreage, “specialty” crops (Fernandez and Smith, 2004). These crops, which include vegetables and fruits, do not generate sufficient profit to justify the significant investment in regulatory compliance, and as a consequence, they have not been the focus of commercial development in recent years.

Another possible barrier to realizing the full potential of transgenic technology for improving cucurbit crops may be the reluctance of the public to consume fresh or raw genetically engineered commodities, especially in countries outside the United States. This barrier has thus far not been a major problem in the commercialization of transgenic squash, but the low level of publicity surrounding this crop may be responsible for this situation. The reaction of the public to more popular cucurbit crops such as melons, watermelons, or cucumbers may prove to be different. This reaction will depend in part upon the success of researchers and educators in providing accurate, credible information about transgenic crops in general.

While the potential for transgenic varieties remains largely unrealized in this family of crops, awaiting a more favorable climate for commercialization, other agricultural biotechnologies such as marker-assisted breeding are making significant contributions. Because of the increasing need for crop improvement in order to help meet the needs of an increasing world population not only for increased food quantity but accompanying nutritional quality, researchers involved in crop improvement will need to use all tools available to them in order to meet these needs within the context of more sustainable agricultural practices.

Alliums

Colin C. Eady and Sarah A. Hunger

New Zealand Institute for Crop and Food Research Limited, Christchurch, New Zealand

1. INTRODUCTION

1.1 History

The cultivation of onion (*Allium cepa*) was first documented 4000 years ago by the ancient Egyptian civilizations (Hanelt, 1990). Since then, over 750 species of *Allium* have been recorded (Stearn, 1992) and the *Allium* species that have become agriculturally important are cultivated extensively for consumption worldwide (Table 1). Their popularity is due to unique sulfur metabolism pathways, which give Alliums their characteristic odor and flavor along with numerous health and nutritional benefits (Randle and Lancaster, 2002). Typical features of this genus include fleshy bulbs, basally arranged leaves, and an umbel-like inflorescence. A wide spectrum of these features is present throughout the genus *Allium*. Among cultivated Alliums, bulb characteristics and shaft length in leeks are highly variable but the other organs remain largely undifferentiated. This reflects intensive selection for a variety of bulb types by breeders (Fritsch and Friesen, 2002).

1.2 Industry

In 2004, worldwide production of onion and garlic was 54.8 and 12.9 million tons, respectively, with the total volume of global Allium crops at 69.3 million tons (FAO, 2007). Production of these two major Allium crops occurs globally throughout 175 countries. However, China is by far the largest

production area, with 30% (16.3 million tons) of the world's onion produce and 69% (8.9 million tons) of the world's garlic produce (FAO, 2007). Other notable areas of Allium production include India (4.9 million tons) and the United States (3.8 million tons). Further statistical data for global Allium production can be found on the FAO Web site (www.fao.org).

Global consumption trends show marked differences, with Asian markets dominated by green onion (*Allium fistulosum*) types, while western markets prefer bulb onion. Also, traditional Asian cultures use all parts of the plant, including bulb, leaf, scape, flower, and occasionally roots, for culinary purposes. New Allium cultivars with unique characteristics and flavors developed through a variety of methods, including traditional breeding (e.g., Vidalia onion and red onion varieties) and genetic modification, will add further value to the industry in the future.

1.3 Allium Flavor Compounds

The unique sulfur metabolic pathway of Allium, highly valued for its health and nutritional benefits, is thought to have evolved for storage and transport of carbon, nitrogen, and sulfur and as a natural form of defense against pests and diseases (Lancaster and Boland, 1990; Ankri and Mirelman, 1999; Jones *et al.*, 2004). Most of the sulfur in Alliums is in the form of nonprotein amino acids (S-alk(en)yl-L-cysteine sulfoxides (ACSOs), γ -glutamyl

Table 1 Commercially important *Allium* species and their common names^(a)

<i>Allium</i> species	Common names
<i>A. cepa</i> L.	Onion Shallot Spring onion Potato onion
<i>A. ampeloprasum</i> L.	Leek
<i>A. porrum</i> L.	Kurrat Great-headed garlic
<i>A. fistulosum</i> L.	Japanese bunching onion Welsh onion Spring onion Shallot
<i>A. x proliferum</i> (Moench) Schrad.	Top onion Tree onion Egyptian onion Catawissa onion Wakegi onion
<i>A. chinense</i> G. Don	Rakkyo
<i>A. sativum</i> L.	Garlic
<i>A. schoenoprasum</i> L.	Chives
<i>A. tuberosum</i> Rottl. ex spr.	Chinese chives

peptides, *S*-substituted cysteines, and cycloalliin) rather than as cysteine and methionine as it is in other plants (Randle and Lancaster, 2002). The unique flavor and odor of Alliums is derived from the hydrolysis of ACSOs, which produces pyruvate, ammonia, and volatile sulfur compounds (Randle and Lancaster, 2002). This reaction is catalyzed by the enzyme alliinase (alliin alkyl-sulphenate-lyase, E.C. 4.4.1.4), which is contained in vacuoles within cells and released upon disruption of the tissue (Lancaster and Collin, 1981). Recently, lachrymatory factor synthase, responsible for the evolution of the lachrymatory factor propanthial *S*-oxide from disrupted tissue, has also been identified (Imai *et al.*, 2002).

Four different ACSOs have been identified in Alliums (Bernhard, 1970): (+)-*S*-methyl-L-cysteine sulfoxide, (+)-*S*-propyl-L-cysteine sulfoxide, *trans*-(+)-*S*-(1-propenyl)-L-cysteine sulfoxide, and (+)-*S*-(2-propenyl)-L-cysteine sulfoxide (2-PECSO or alliin). Variations in the ratios of these volatile sulfur compounds are responsible for the difference in flavors and odors between *Allium* species (Randle and Lancaster, 2002).

Fructans and quercetins are also important flavor components of Alliums. Fructans are

water-soluble carbohydrates that, during low-temperature storage, are gradually hydrolyzed to fructose for synthesizing sucrose at the initiation of sprouting (Pak *et al.*, 1995). Varying ratios of the soluble carbohydrate component of onion bulbs influence the osmotic potential, sweetness, and storage qualities over a wide variety of cultivars (Sinclair *et al.*, 1995a, b). For example, fructan content is low in sweet and low dry matter varieties of onion and high in storage-type onions such as US cv. "Sentinel" (Salama *et al.*, 1990). Quercetins, such as quercetin 3,4'-*O*-diglucoside and quercetin 4'-*O*-monoglucoside, are the major flavonol glucosides in onion (Price and Rhodes, 1996). Along with health and nutritional benefits associated with these compounds (Keusgen, 2002), these polyphenols are also major contributors to the bitter taste of some onions (Lugasi *et al.*, 2003). The oxidation of quercetins produces the antifungal agent dihydrobenzoic acid in the protective skins of onion (Takahama and Hirota, 2000).

1.4 Allium Cultivation and Traditional Breeding

The intensive breeding regime that has led to the development of the cultivated *Allium* crops in routine agricultural production today has resulted in significant deviations from wild *Allium* relatives. As such, many cultivated *Allium* crops require highly specific agronomic conditions for maximum yields. Onion is predominantly a biennial crop and can be propagated by seeds, bulbs, or sets (Brewster, 1994). Seed is sown in spring or mid to late winter with seedlings emerging in the first 2 weeks after sowing. The first true leaf appears after 4–10 weeks. Bulb formation is initiated in response to specific temperature and photoperiod cues, which vary between cultivars (Brewster, 1994). Bulb onions are broadly divided into three classes (i.e., long, mid, and short day-length/temperature) based on this differentiation. Bulbs aestivate in summer then sprout in autumn to produce flowers the following summer, which set seed in late summer to early autumn. For a comprehensive coverage of onion agronomy the reader is referred to Bosch Serra and Currah (2002). Glasshouse cultivation of onion is possible. However, it is fraught with difficulties as the

hot humid conditions render the plants highly susceptible to disease and provide a predator-free environment for insect pests to thrive.

Although true garlic seeds have been generated (Etoh *et al.*, 1988; Pooler and Simon, 1994), the absence of large sources of true seed garlic has led to the development of an industry heavily reliant on clonal propagation, with its associated pitfalls for this crop (Etoh and Simon, 2002). On the other hand, leek production has, until recently, relied on open-pollinated commercial cultivars with poor uniformity (De Clercq and van Bockstaele, 2002). Recent improvements in leek seed quality have been achieved through the implementation of seed priming, which increases seed germination and the rate of seedling emergence, improves early plant growth, and increases the crop uniformity in the field (De Clercq and van Bockstaele, 2002). In the past, commercial onion breeding lines have been derived from open-pollinated populations with high levels of genetic variation. However, they are increasingly being produced from hybrid lines (reviewed by Sidhu *et al.*, 2004). The development of doubled haploid and inbred onion lines is also currently underway to produce cultivars with much higher levels of uniformity (Bohanec, 2002).

Sterility or poor fertility in interspecific hybrids makes it difficult to transfer characteristics between *Allium* varieties or species. Also, recovering hybrid lines that show the introduced trait while retaining the original desirable characteristics (e.g., bulb onions) can take many years due to the biennial nature of this crop (Cramer and Havey, 1999). Further advances in the development of interspecific hybrids in the future will enable many of these challenges to be overcome. Mapping of molecular markers linked to desirable traits such as specific day-length response, bulb size, pungency, storage ability, hardness, dry matter content, and resistance to pests and diseases in the onion genome has also helped to advance traditional breeding methods (King *et al.*, 1998; Heusden *et al.*, 2000; Martin *et al.*, 2005).

1.5 Justification for Germplasm Modification

The ability to genetically modify onion to express specific traits may overcome some of the difficulties associated with traditional breeding.

Genetic modification would allow the introduction of traits to *Allium* germplasm that would otherwise be extremely difficult or impossible to improve by traditional breeding techniques. The late development of the technology to achieve genetically modified *Allium* germplasm is beneficial, as researchers can take advantage of prior studies performed in other crop species since the 1980s, thereby reducing the risk that this technology will fail to deliver economic returns (Eady, 2001a).

2. CURRENT APPLICATIONS OF ALLIUM TRANSFORMATION

2.1 Herbicide Resistance

Herbicide-resistant onion germplasm has now been developed (Figure 1). This work has concentrated on the use of the *CP-4*-derived gene constructs to confer resistance to the systemic herbicide glyphosate (Eady *et al.*, 2003a). The enolpyruvylshikimate-3-phosphate synthase (EPSPS) enzyme, which is involved in the production of aromatic amino acids in plants, is inhibited by glyphosate. Tolerance to glyphosate is achieved either through the overexpression of the *CP-4* EPSPS enzyme (Hetherington *et al.*, 1999) or by detoxification of the glyphosate by either the glyphosate oxidoreductase (*GOX*) gene or the glyphosate acetyl transferase (*GAT*) gene. For a detailed review of glyphosate-resistant crops, the reader is referred to Dill (2005). Initial results in onion indicate that the *CP-4*-derived gene is stable and constitutively expressed and is functioning as expected in onion (Davis *et al.*, 2006). Savings in herbicide usage of up to 75% for this crop have been projected (Eady, 2001b). In addition, glyphosate is a short-lived, low-toxicity herbicide compared with many of the persistent toxic herbicides that are currently used.

For experimental purposes, gene constructs containing the *bar* gene have also been introduced to demonstrate that plants resistant to the contact herbicide phosphinothricin can also be produced (Eady *et al.*, 2003a). The *bar* gene encodes a phosphinothricin acetyltransferase enzyme from *Streptomyces hygroscopicus*, which detoxifies the herbicide (Vinnemier *et al.*, 1995).

Figure 1 (a) Unsprayed nontransgenic onions; (b) herbicide-resistant germplasm sprayed with 2× recommended glyphosate rate for general weed control; (c) nontransgenic sibling plants sprayed with 2× glyphosate rate for general weed control; (d) nontransgenic siblings, hand weeded

Stable inheritance of this gene into the first filial generation has also been demonstrated (Eady *et al.*, 2003b).

2.2 Disease Resistance

Advances in biotechnology have led to the identification of many genes involved in plant defense mechanisms, and other genes from a broad range of organisms useful for improving plant disease resistance (reviewed by Punja, 2001). Recent research has focused on improving resistance to *Sclerotium cepivorum* (Berk.), the causative agent

of Allium white rot, through overexpression of a germin protein with oxalate oxidase (OXO) activity (Bidney *et al.*, 1999) and the antimicrobial magainin (MGD) peptide (Zasloff, 1987; Zasloff *et al.*, 1988) in onion. OXO (oxalate oxygen oxidoreductase, E.C. 1.2.3.4) degrades oxalic acid, the fungal toxin produced by *S. cepivorum* and many other plant fungal pathogens, to form carbon dioxide, hydrogen peroxide, and oxygen. The concomitant production of hydrogen peroxide further enhances the plant's resistance (Peng and Kuc, 1992; Brisson *et al.*, 1994; Levine *et al.*, 1994). MGD peptides act by preferentially integrating into acidic phospholipid bilayers of microbial

membranes (cf. zwitterionic lipids of mammalian cell membranes), thus destabilizing the cell membranes and causing cell lysis (Matsuzaki, 1998). Future research will use a rapid high-throughput assessment system that has also been developed (Hunger *et al.*, 2002) to demonstrate the effectiveness of these genetic modifications in onion against *S. cepivorum* (Figure 2).

The tospovirus Iris yellow spot virus is an emerging disease of Allium crops that is spreading rapidly (du Toit *et al.*, 2004; Schwartz *et al.*, 2007). DNA sequence information from this virus has been isolated (Pappu *et al.*, 2006), which, in combination with gene silencing technology, could be used to control this disease in the future. Indeed, multiple tospoviruses have already been targeted and successfully controlled in tomato using gene silencing (Bucher *et al.*, 2006).

Garlic mosaic disease, caused principally by the potyviruses leek yellow stripe virus and onion yellow dwarf virus, is another major viral disease of Alliums (Takaki *et al.*, 2005). The development of gene silencing technology to combat this disease in garlic would revolutionize this industry, which currently relies on costly continual regeneration of virus-free meristematic cultures in order to avoid the proliferation of garlic mosaic disease.

2.3 Insect Resistance

Crop Alliums can suffer damage from a variety of insect pests depending on their geographical location (Soni and Ellis, 1990). Some of these pests are generalist grazers, such as thrips, for which it is likely to be difficult to develop a simple genetic basis of resistance. However, for others, such as the beet armyworm (*Spodoptera exigua* Hübner) and onion maggot, it should be possible to develop effective transgenic approaches (Eady, 2002a; Ramputh *et al.*, 2002). Indeed, transgenic garlic containing the *Bacillus thuringiensis cry1Ca* and *H04* hybrid gene constructs produced at the Plant Research International (PRI), Wageningen, showed complete resistance to beet armyworm (Zheng *et al.*, 2004).

2.4 RNA Interference

The sulfur and carbohydrate pathways of the *Allium* genus cause some of the unique nutraceutical qualities ascribed to garlic and onions (reviewed by Block (1992), Hell (1997), Leustek and Saito (1999), and Randle and Lancaster (2002) for sulfur, and Darbyshire and Steer (1990)

Figure 2 (a) Nontransgenic onion root 24 h after contact with a pregerminated sclerotia; the black bar indicates the oxalic acid induced necrotic zone; (b) transgenic onion root expressing the OXO gene 24 h after contact with a pregerminated sclerotia; the black bar indicates the much reduced necrotic zone

for carbohydrate). Gene discovery programs, dedicated to identifying the candidate genes playing a role in regulation of these pathways, have been established in several laboratories around the world (van Heusden *et al.*, 2000; Galmarini *et al.*, 2001; McCallum *et al.*, 2001). Candidate genes identified as being involved in these pathways are being used to build RNA interference (RNAi) constructs in order to silence specific genes in the onion genome so that their role in sulfur and carbohydrate regulation can be determined. Plants are currently being developed with RNAi constructs directed against serine acetyl transferase and γ -glutamyl cysteine synthetase genes in the S-pathway and sucrose phosphate synthetase in the carbohydrate pathway (C.C. Eady and J.A. McCallum, personnel communication). To date only one gene, the *alliinase* gene, has been silenced using antisense technology (Eady, 2002b). Although some of these lines appeared to have reduced pungency, the phenomenon was also linked to low solids content, which made quantifying pungency difficult.

2.5 Targeted Transgene Expression

Expression of transgenes in transgenic plants is generally driven by constitutive promoters of viral origin, which produce high levels of gene expression throughout all plant tissues, e.g., cauliflower mosaic virus 35S (CaMV 35S) promoter (Kay *et al.*, 1987), or cestrum yellow leaf curling virus promoter (Stavolone *et al.*, 2003). Our group is currently investigating a promoter that could potentially produce high levels of disease resistance transgene expression in the roots of onion plants at the site of *S. cepivorum* infection. The use of a native onion promoter to drive transgene expression in onion would be desirable because much of the debate surrounding the use of genetic modification to enhance food crops focuses on the introduction of foreign transgenes into an organism. The newly emerging field of intragenics, in which all of the genetic material used to enhance crop species by genetic modification derives from the host plant genome (Conner *et al.*, 2006), addresses this issue directly. Intragenics redefines genetically modified organisms so that they can no longer technically be considered “transgenic” (Conner *et al.*, 2006).

2.6 Overview of Allium Transformation

Allium species have proven recalcitrant to genetic transformation and regeneration (Eady, 1995; Eady *et al.*, 1996). This is attributed to their unusually large genome (15 290 Mbp/1C), which is 107 times larger than *Arabidopsis* (115 Mbp/1C; Arumuganathan and Earle, 1991), the limited tissue types from which plants will regenerate, low transformation efficiencies, and the precision required for post-transformation selection protocols (Eady, 2002a). As such, this genus is amongst the last commercially important vegetable genera for which gene transformation protocols have been developed. Despite these caveats, DNA has been successfully delivered into onion (Klein *et al.*, 1987; Dommissie *et al.*, 1990; Eady *et al.*, 1996). However, these techniques did not succeed in producing transgenic onion plants. To date, efforts to develop routine transformation protocols have largely focused on onion, the most economically important of the three main cultivated *Allium* species (Eady, 1995; Eady *et al.*, 1996; Barandiaran *et al.*, 1998). Transformation protocols have also been developed for leek (Eady *et al.*, 2005) and garlic (Kondo *et al.*, 2000; Eady *et al.*, 2005). However, these are still in their infancy.

Since monocotyledons are not natural hosts of *A. tumefaciens*, direct DNA delivery to onion tissue through biolistic transfer was initially investigated (Eady *et al.*, 1996). However, low transformation efficiencies and reports of unusual transfer-DNA (T-DNA) integration patterns using biolistics (Songstad *et al.*, 1995) resulted in limited success using this approach (Eady *et al.*, 1996). Later, more precise, stable T-DNA integration into monocotyledonous plants by *A. tumefaciens*-mediated transformation was developed (Hiei *et al.*, 1997). This was the catalyst for the development of the first successful routine transformation protocol for onion by Eady *et al.* (2000). Since then, there have been several further reports of *Agrobacterium*-mediated transformation of onion (Zheng *et al.*, 2001b; Bastar *et al.*, 2003; Aswath *et al.*, 2006). However, the protocol developed by Eady *et al.* (2000) is the only routine onion transformation protocol available for production of transgenic onion plants through the selection and proliferation of transgenic embryogenic cultures.

The consistent yield of transformants, albeit at low efficiencies (<2.75%), from the protocol of Eady *et al.* (2000) has been attributed to the use of immature embryos. Immature embryo cells are very plastic with regard to regeneration and differentiation (Eady *et al.*, 1998) and have a cell wall structure that is thought to be more amenable to *Agrobacterium* attachment than the cell walls of other monocotyledonous tissues (Mankarios *et al.*, 1980; Dommissie *et al.*, 1990). These cells are transformed after wounding and co-cultivation with *A. tumefaciens*. In this system, the initial transgenic cells are dependent on the surrounding nontransgenic tissue (Eady, 2002a). Thus, the stringency of the selective agents applied during the recovery of transgenic onion cultures is critically important (Eady and Lister, 1998).

Other researchers have transformed alternative tissue types with limited success. Zheng *et al.* (2001b) transformed 3-week-old cultures produced from zygotic embryos extracted from mature seed and achieved a maximum transformation rate of only 0.53% in onions and up to 1.95% in shallots. Bastar *et al.* (2003) transformed organogenic structures precultured from onion ovaries but obtained chimeric plants showing transgene expression in superficial tissue layers only (Bohanec, 2003). Aswath *et al.* (2006) transformed embryogenic callus from seedling radicle using both *Agrobacterium*-mediated and biolistic DNA transfer. Although these authors report a phenomenally high rate of plantlet regeneration (27 and 23%, respectively; Aswath *et al.*, 2006), they present no picture of phenotypically normal, mature transgenic onion plants.

2.6.1 Onion transformation protocol

The transformation procedure outlined below is used routinely in the Crop & Food Research Laboratory at present and is based on that developed by Eady *et al.* (2000). Although the rate of mature transgenic plant regeneration is low using this protocol (up to 2.7%), it is reliable and reasonably consistent on a seasonal basis. For other onion transformation protocols in the literature, the reader is referred to Zheng *et al.* (2001b) and Aswath *et al.* (2006).

2.6.1.1 Bacterial strain and plasmids

Agrobacterium tumefaciens strain LBA4404, with the binary vector pBIN or pCambia derivatives, and possessing within its T-DNA the selectable genes *nptII* (neomycin phosphotransferase II) or *hyg* (hygromycin) and the visual reporter genes *uidA* (β -glucuronidase) or *m-gfpER*, were used in Allium transformation experiments. Transgenic onion plants containing genes that confer resistance to the herbicides glyphosate or phosphinothricin were also introduced into onion (Eady, 2002b). To generate glyphosate-tolerant plants, *A. tumefaciens* strain ABI was used, containing a binary vector that included the *CP-4*-derived gene within the T-DNA (kindly supplied by Monsanto Corp.). To generate plants tolerant to phosphinothricin, the *A. tumefaciens* strain LBA4404 that contained a binary vector pCambia 3301 (from Commonwealth Scientific and Industrial Research Organisation (CSIRO), Canberra) with the *bar* gene within the T-DNA was used. In experiments to date, expression was driven by either the CaMV 35S (Eady, 2002b) or *nos* (nopaline synthase) promoter (Zheng *et al.*, 2001b).

2.6.1.2 Transformation procedure

Day 1. *Agrobacterium* cultures were initiated by inoculating 50 ml of Luria broth (LB) media containing appropriate selective agents, in a 100 ml flask, with 1 ml of frozen stock (0.7 ml of actively growing culture plus 0.3 ml of 50% glycerol stored in 1 ml aliquots at -80°C), then incubated overnight at 28°C with agitation at ~ 125 rpm.

Field-grown umbels of *A. cepa* L. were used as a source of plant material from which approximately 12 g of immature seed was isolated. The isolated seed was stored overnight at 4°C in a 50-ml vial covered with wet tissue.

Day 2. The *Agrobacterium* cultures were replenished with an equal volume of LB containing antibiotic and $100\ \mu\text{M}$ acetosyringone (virulence gene inducing factor), then incubated at 28°C with agitation at ~ 125 rpm for a further 4–5 h. The optical density was adjusted to approximately 0.4 at 550 nm by the addition of LB. After the immature embryos were isolated (see below), *Agrobacteria* were pelleted in 15-ml falcon tubes

by centrifugation at 4000 rpm, then resuspended in an equal volume of liquid plant culture media, P5, containing 200 μ M acetosyringone.

Isolated immature seeds were washed for 1 min in ethanol and then surface sterilized in 50 ml of 30% household bleach solution, plus 1 drop of Tween-100, for 30 min with gentle agitation at \sim 25–50 rpm. After washing four times in sterile water and draining for 2 min, immature embryos were isolated from the seed by stereo microscope (Eady *et al.*, 1998). Large translucent embryos (2–5 mm in length), isolated from seed that had recently turned black with a liquid endosperm, were the most responsive to treatment. Embryos were isolated in batches of 50 then cut into \sim 1 mm lengths and stored in 50 μ l of liquid P5 (Eady *et al.*, 1998) in a 1.8-ml microfuge tube until \sim 1000 embryos had been isolated.

Four hundred microliters of *Agrobacteria* culture was added to each 1.8-ml microfuge tube, then the tube was vortexed for 30 s. The lid of the microfuge tube was pierced with a sterile scalpel blade, then the tube was placed under vacuum (\sim 25 mmHg) for 30 min. The excess liquid *Agrobacteria* culture was aspirated off using a 200- μ l pipette, then the immature embryo tissue pieces carefully transferred to filter paper and left to drain briefly, in a clump, before being transferred to P5 media and carefully being distributed with fine tweezers over the surface of a 90-mm petridish containing solid P5 medium (two batches per petridish). It was important to make sure that there was no excess moisture on the surface of the P5 media at this point as this caused liquid to pool around the embryo, which reduced embryo survival. After transfer, the petridishes were sealed with household polythene wrap and incubated in the dark at 24–26 $^{\circ}$ C in a growth room.

Day 8. After 6 days' co-cultivation, the embryogenic tissue was transferred to P5 containing timentin (200–250 mg l^{-1}) to kill the *Agrobacteria* and the appropriate selective agents to select for the transgenic tissue. The embryogenic sectors were cultured in the dark under the conditions described above for 12 weeks, transferring to fresh medium every fortnight. The use of timentin could normally be discontinued by week 6–8. However, it was necessary to watch carefully for any latent *Agrobacteria* overgrowth after this time. Clean tissue was immediately transferred to media containing 250 mg l^{-1} timentin in the

event of any observed *Agrobacteria* overgrowth. It was necessary to maintain timentin levels through to transfer to shoot media with experiments using the ABI strain as it was more virulent than LBA4404 and, thus, more prone to overgrowth.

Selection for 4 weeks on 12 mg l^{-1} of geneticin, followed by 8 weeks at 20 mg l^{-1} of geneticin, was found to be optimal for the regeneration of transgenic onion tissue sectors containing the *nptII* gene. The selection regime for transgenic onion tissue sectors treated with the *CP-4*-derived gene comprised 0.025 mM glyphosate and 250 mg l^{-1} timentin. The glyphosate level was raised to 0.05 mM after 6–8 weeks' selection and maintained at this level throughout selection and regeneration. For the selection of phosphinothricin-tolerant tissue, co-cultivated embryos were initially transferred to P5 media containing 5 mg l^{-1} phosphinothricin and 250 mg l^{-1} timentin. The phosphinothricin was maintained at this level throughout selection and regeneration.

From day 8 onward, it was possible to observe any transgenic material containing the *m-gfpER* gene using a fluorescence microscope by observation of the tissue under 440–480 nm excitation and 510 emission (Leffel *et al.*, 1997; Eady *et al.*, 2000). If *uidA* visual reporter gene was used then tissue had to be sacrificed and stained (Eady *et al.*, 1996; Zheng *et al.*, 2001b).

Week 13. After 12 weeks of selection, actively growing material was transferred to regeneration medium (Eady *et al.*, 1998) containing 20 mg l^{-1} geneticin. (This time period could be reduced to 8 weeks if the visual *m-gfpER* marker was also used to identify transgenic tissue.) Shoot cultures were maintained for 12 weeks under 16-h day-length through 3 weekly subculture.

Week 19 onward. Developing shoots were transferred to $1/2$ Murashige and Skoog (MS) media (Murashige and Skoog, 1962) plus selective agents and maintained as above to induce rooting. *In vitro* culture response was varied and some transgenic sectors proliferated to produce hundreds of shoots on regeneration media, whereas others failed to produce shoots or produced only a few. Maintenance for long periods (>6 months) *in vitro* resulted in a decline in regeneration capability and an increase in the degree of hyperhydricity shown by the cultures (Eady *et al.*, 1998). It was possible to induce *in*

vitro bulbs by subculturing the plantlets on $1/2$ MS medium plus 120 g l^{-1} of sucrose (Seabrook, 1994).

2.6.1.3 Ex-flasking and growth in containment

Transferring the primary transformant from *in vitro* culture to the glasshouse is often a technically difficult process. Fortunately, onion plantlets in culture are quite robust and there are numerous reports of successful transfer to the glasshouse (Novak, 1990; Eady, 1995). Rooted plants were carefully washed to remove any attached agar and transferred to a 1:1:1 perlite:bark:compost mix containing 400 g dolomite, 300 g Osmocote, 75 g superphosphate, and 50 g sulphate of potash per 50 l in the glasshouse (12 h, 12–23 °C day; 12 h, 4–16 °C night).

Although ex-flasking has proved relatively easy in onions, maintenance within transgenic containment facilities can be a problem. For correct chilling and flowering, it is preferable to grow them within a shade house. In wet winters and in spring in the wet, the still air in such shade houses is conducive to scarab fly infestations and infection by a host of bacterial and fungal pathogens. Bulb formation in glasshouse-grown plants was induced naturally by increasing the day-length. After 50% of the tops had fallen, bulbs were lifted and air dried. Bulbs were rested for 2 months in a dry environment and then either cold stored to induce floral meristems prior to planting in the spring or replanted in large pots and grown in a containment shade house over winter, spring, and summer, in order to produce flowers.

Transgenic plants were self-fertilized by bagging the umbel (within a microperforated plastic bread bag) as the flowers start to open. Approximately 20–50 flies or ready-to-hatch pupae (*Lucilia cuprina*) were then introduced into the bag and left until all flowers had finished opening (occasionally the introduction of additional flies was necessary). Crossing on to nontransgenic plants was achieved by flowering plants in $1 \text{ m} \times 1 \text{ m} \times 2 \text{ m}$ high cages with flies or bees introduced to effect pollination.

After all the flowers were pollinated, the umbel was left to ripen. As the umbels ripen, the ovary walls containing the seed start to crack open. At this point, the umbels were harvested and air dried

in large 1-mm mesh bags for 1 month. Seeds were then separated from the chaff and either stored (viability drops dramatically in onions unless stored properly) or germinated immediately for further investigation.

2.6.2 Leek transformation

The onion transformation protocol described above was, for the first time, successfully applied to leek immature embryos to demonstrate the stable transformation of leek (Eady *et al.*, 2005).

Immature umbels of leek are more difficult to extract because the ovary wall tissue is tougher and more slippery than onion ovary wall tissue. In addition, when the seeds are at the correct developmental stage, they bleach upon sterilization. This does not affect the viability of the embryo. Initial embryo treatment and co-cultivation followed the onion transformation protocol described in Section 2.6.1.2. Selection and regeneration was performed on geneticin using only one level of selection (12 mg l^{-1}). It should be noted that leek embryo response to P5 media was markedly different to that of onion. The majority of leek embryos rapidly elongated and failed to form an embryogenic culture. This reduction in embryogenic response most probably caused the observed reduction in transformation efficiency in leek compared with onion. Initial gene transfer, as determined by observations of transient *gfp* expression, appeared similar to that observed in commercial lines of onion, but less than that observed in the open-pollinated Canterbury Longkeeper (CLK) lines with which the onion transformation procedure was developed.

2.6.3 Garlic transformation protocol

The onion transformation protocol described above was also successfully applied to immature embryos extracted from true seed garlic (Eady *et al.*, 2005). Two plant lines were produced from four experiments, in which approximately 3200 embryos were isolated, equating to a transformation efficiency of approximately 0.06% (Eady *et al.*, 2005). Garlic immature embryos responded to selection and culture in a similar manner to onions (cf. leek). However, a large proportion

of the immature embryos (approximately 50% in some experiments) failed to produce embryogenic cultures, instead developing elongated cotyledons (similar to etiolated seedlings) in response to the P5 medium. Transgenic embryogenic cultures that regenerated successfully on selective medium eventually formed roots in *in vitro* culture (albeit at a much slower rate than transgenic onion cultures). These plantlets were easily transferred to the glasshouse and developed to maturity, producing both cloves and topsets (Eady *et al.*, 2005). For a garlic transformation protocol that is not reliant upon true seed garlic, the reader is referred to Kondo *et al.* (2000).

2.7 The Challenges of Allium Transformation

2.7.1 Embryogenic material

Although transformation rates in the New Zealand CLK onions are generally better than in other cultivars, it seems that only a small proportion of the highly genetically variable onion embryos used in the experiments have a genetic background that is receptive to T-DNA transfer. CLK is a heterozygous, open-pollinated cultivar in which every embryo is genotypically unique. Therefore, within this gene pool there are presumably certain genotypes that are more receptive to genetic transformation and regeneration. Isolation of receptive genotypes through the rescue of transformable cultures is currently underway. The production of doubled haploid lines from cultures with a receptive genetic background may permit the identification of homozygous lines that are highly receptive to genetic transformation. Genetic transformation into a homozygous genetic background permits detailed analysis of the effect of transgenes on the original plant phenotype, in the absence of naturally high levels of genetic variation, which otherwise make such investigations difficult. Currently, research using inbred dehydrator onion lines is underway to investigate more specifically the effects of introduced genes and the transformation procedure.

Embryo health and the development stage prior to harvest are important factors influencing the seasonal transformation rate. There appears to be an optimal stage of development at which

the embryo is most receptive to transformation. This optimal development stage is difficult to define and isolate specifically due to the low transformation frequency, rapid rate of embryo development *in vivo*, and limited ability to identify suboptimal embryos during the isolation process. Seasonal environmental variations have a large impact on these factors, as the maturation rate of embryos is very rapid in hot conditions, whereas wet, cool conditions promote the development of disease and poor embryo health. Also, onions are problematic to grow in the glasshouse, making it difficult to control seasonal variation between years by growing them in standard conditions.

2.7.2 External variables

External variables such as operator skill and environmental conditions also impact on the embryo transformation rate. Operator skill and minor changes in the wounding process have a significant impact on the rate of transformation as shown by a reduction in the initial rate of transient *gfp* expression after the co-cultivation period in embryos transformed by inexperienced operators. The location of the wound in the embryo is important because it is thought that the shoot meristematic cells and the cells surrounding this area are the most receptive to transformation and regeneration. Therefore, specific wounding of these cells is important for T-DNA transfer (Hiei *et al.*, 1997).

2.7.3 Selection systems

The development of a selection regime is difficult with embryogenic onion cultures, because the transgenic cells are initially dependent on other nontransgenic cell types within the culture. Thus, the selection regime must not kill the nontransgenic tissue in the culture until the transgenic cells can be “weaned” from the supporting nontransgenic cells to become independent transgenic cultures (Todd and Tague, 2001). To date, the herbicides L-phosphinothricin (PPT) and glyphosate (Eady *et al.*, 2003a), the antibiotics geneticin (G418) (Eady *et al.*, 2000) and hygromycin (Zheng *et al.*, 2001b) and the metabolic selectable marker phosphomannose isomerase (Hunger, 2007) have

been successfully used as selection agents to recover transgenic onions.

2.7.3.1 Antibiotic selection

Until recently, the selection of transgenic plants has largely been based on the use of antibiotic markers (Cheng *et al.*, 2004). These are predominantly aminoglycoside antibiotics, such as kanamycin, geneticin, neomycin, paromomycin, and hygromycin, which bind to ribosomes involved in protein synthesis in prokaryotic cells, mitochondria, and chloroplasts (Wilmink and Dons, 1993). Some public groups oppose the use of broad-spectrum aminoglycoside antibiotics in biotechnology. The other disadvantage with this approach is the “leaky” nature of the geneticin selection system in onion, which only works well in conjunction with the *gfp* visual reporter gene (Eady and Lister, 1998). These issues make the use of antibiotic resistance selectable marker genes undesirable in applied research.

Although selection on geneticin is leaky in onion, it is still used routinely as a selective agent in our research group. Geneticin acts by binding to the 30S ribosome, blocking protein synthesis in eukaryotic cells (Wilmink and Dons, 1993). Resistance to geneticin is conferred by the NPTII enzyme. When a chimeric version of the *nptII* gene (Bevan, 1984) is expressed in transgenic plants, members of the aminoglycoside group of antibiotics, which includes geneticin, are disabled by phosphorylation (Wilmink and Dons, 1993).

2.7.3.2 Herbicide selection

Herbicide-based selection is an alternative nonantibiotic, negative selection approach in which tolerance to the herbicides PPT or glyphosate is conferred to the transgenic tissue. Glyphosate is currently the only truly effective selection agent for the regeneration of transgenic onion plants without the concomitant regeneration of escapes (Eady *et al.*, 2003a). Herbicide-based selection is not popular with some public groups, owing to their concerns about the transfer of herbicide resistance traits to weedy plant species. These concerns are largely unjustified in onion due to

poor ability of onion to hybridize or breed with other species (Kik, 2002).

2.7.3.3 Mannose selection

The Positech[®] selection system enables plants expressing the phosphomannose isomerase (*pmi*) gene, derived from the *Escherichia coli manA* gene (Miles and Guest, 1984), to convert mannose-6-phosphate into the usable carbon source, fructose-6-phosphate; by contrast, the phosphorylation of mannose to mannose-6-phosphate by hexokinase in nontransgenic tissue depletes stores of phosphate and adenosine triphosphate (ATP) (Sheu-Hwa *et al.*, 1975). Thus, transgenic tissue proliferates on media containing mannose, whereas nontransformed tissue either stops growing or dies of starvation (Hansen and Wright, 1999). Selection on mannose has been reported to improve the transformation rate severalfold in numerous plant species (e.g., wheat (Wright *et al.*, 2001), maize (Negrotto *et al.*, 2000), and sugar beet (Joersbo *et al.*, 1999).

Optimal levels of selection are essential for a successful transformation protocol (Hiei *et al.*, 1997; Cheng *et al.*, 2004). This is especially true of recalcitrant crops from which the identification and selection of a small proportion of transgenic tissue from large amounts of nontransgenic tissue is required. To date, only negative selection systems that “kill” nontransgenic tissue (e.g., antibiotics and herbicides) have been used to recover transgenic onions. With negative selection, if the selection criteria are too moderate then the nontransgenic tissue will proliferate and outcompete the transgenic tissue, whereas if the selection criteria are too stringent they may be detrimental to the growth of transgenic tissue. Identifying appropriate stringency for selection is very important in the embryogenic culture system used in this research, in which transgenic tissue is initially dependent upon surrounding nontransgenic tissue (Eady *et al.*, 2000).

Selection on mannose is based on the premise that transgenic tissue with the ability to use this compound as a carbohydrate source will be positively selected for and outcompete nontransgenic tissue that is unable to metabolize mannose. The accumulation of mannose within the plant cell

itself is not directly toxic, but the depletion of phosphate stores as the mannose is phosphorylated to mannose-6-phosphate eventually starves the cell to death (Hansen and Wright, 1999). However, the presence of other metabolizable sugars in the growth medium ameliorates the starvation effect (Joersbo *et al.*, 1999; Wright *et al.*, 2001). Other nonantibiotic positive selection systems do exist, including those based on benzyladenine N-3-glucuronide (Joersbo and Okkels, 1996), 2-deoxyglucose (Kunze *et al.*, 2001), and xylose (Haldrup *et al.*, 1998). However, mannose-based selection is better than other methods as it is more economical, is functional as an additive in both *in vitro* growth medium and soil (Todd and Tague, 2001), is not toxic or allergenic (Reed *et al.*, 2001), and is reported to significantly increase transformation efficiencies (Wright *et al.*, 2001).

Determining the minimum concentrations of mannose required to prevent regeneration of nontransgenic onion plants was used to develop a selection regime for onion transformation experiments. Initially, 2.5–5 g l⁻¹ of sucrose was included with 10 g l⁻¹ mannose as in other mannose-based selection regimes (Joersbo *et al.*, 1999). However, although it was possible to discern a difference between embryogenic cultures and plantlets grown with various levels of mannose and sucrose and those grown on sucrose alone, it was not sufficient to identify transgenic tissue from nontransgenic tissue. Indeed, the repression of onion tissue growth by mannose appeared to have been reversed by the addition of sucrose as observed by Joersbo *et al.* (1999). The most effective growth inhibition of onion tissue was observed on growth medium containing 15 g l⁻¹ mannose without sucrose. However, growth of nontransgenic embryogenic cultures was still evident on this medium, albeit at a slower rate than that of clonal embryogenic cultures grown on sucrose. Also, there were no obvious phenotypic differences between the two sets of clonal cultures grown on each type of medium. Thus, it became apparent that nontransgenic tissue cultured on mannose was largely insensitive to this selection. Based on these observations, a selection regime of 15 g l⁻¹ mannose without sucrose from 2-week post-transformation to rooting was developed, which permitted the regeneration of transgenic plants with the concomitant regeneration of escapes.

The only apparent explanation for the growth of nontransgenic onion embryogenic cultures on mannose in the absence of other metabolizable sugars and photosynthesis is the metabolism of mannose. Thus, it seems feasible that endogenous enzymes may be active in onion tissue. However, the presence of such enzymes remains highly speculative in the absence of DNA sequence data. Tolerance of mannose has also been reported in other crop species such as carrot, tomato, tobacco, soybean, and a few other legumes (Aragão and Brasileiro, 2002). This was associated with endogenous PMI activity in the soybean and legumes (Gao *et al.*, 2005).

Many reports of selection of transgenic plants on mannose are favorable, with researchers reporting improved transformation efficiencies with this strategy in wheat (Wright *et al.*, 2001), maize (Negrotto *et al.*, 2000), sugar beet, (Joersbo *et al.*, 1999), pearl millet (O'Kennedy *et al.*, 2004), and sorghum (Gao *et al.*, 2005). However, our observations suggest that, while it is possible to recover transgenic onions using this system, it is problematic (Hunger, 2007). The Allium transformation research group from PRI, Wageningen, also reported problems with this system in onion and shallot (S.-J. Zheng, personal communication). A recent publication reports successful selection of transformed onion expressing the *pmi* transgene on mannose (Aswath *et al.*, 2006). However, Aswath *et al.* (2006) did not confirm the production of mature, healthy transgenic plants with this system.

2.7.3.4 Visual reporter genes

The use of a visual marker gene, such as the gene for green fluorescent protein (*m-gfpER*; Haseloff *et al.*, 1997), enables the development of transgenic tissue sectors to be monitored ensuring that cell proliferation in the transgenic sector has become established prior to exposure to more stringent selection conditions. The *m-gfpER* gene cassette targets GFP (green fluorescent protein) to the endoplasmic reticulum, where it accumulates, resulting in high levels of fluorescence when visualized under fluorescent light (395 nm excitation, 509 nm emission) (Haseloff *et al.*, 1997). Destructive sampling and lengthy staining protocols that limit other marker genes such as

the gene for the β -glucuronidase (GUS) enzyme (Jefferson, 1987) and luciferase (Van Leeuwen *et al.*, 2000) are not necessary.

The OXO gene was used as a reporter gene in onion using a staining technique described by Simmonds *et al.* (2004). Plant tissue expressing OXO was stained purple by the oxidation of oxalate into hydrogen peroxide and carbon dioxide, which yields a purple precipitate in a linked reaction by peroxidase in the presence of 4-chloronaphthol. Staining was observed after 5 min in tissue with high levels of OXO expression, such as germinating wheat grains, which were used as a positive control (Hunger, 2007). Although the stain intensity is directly proportional to the quantity of OXO present in the plant tissues, the quantity of OXO in plant tissues required for protection against invading pathogens has not yet been defined. To date, researchers have used *in vitro* spectrophotometric methods to measure the amount of OXO present in plant tissues and reported this value with the improvement in resistance to infection (Donaldson *et al.*, 2001).

2.7.4 Regeneration

High initial transformation rates in onion are often significantly reduced during abnormal plantlet regeneration *in vitro*. This is reflected in the onion transformation literature in which all onion transformation groups report the production of only a few plant lines from numerous transformation initials (Zheng *et al.*, 2001b; Bastar *et al.*, 2003; Aswath *et al.*, 2006). Many transgenic sectors of embryogenic tissue formed roots on shooting medium in our research. These structures seldom produce normal shoots under these circumstances. It is not clear why this occurs, although genotype and the duration of *in vitro* regeneration (as shown by the increasing difficulty of recovering phenotypically normal plants from older cultures) are also likely to be important variables in this process.

Several systems for the recovery of transgenic onion plants are reported in the literature (Eady *et al.*, 2000; Zheng *et al.*, 2001b; Bastar *et al.*, 2003; Aswath *et al.*, 2006). Zheng *et al.* (2001b) regenerated four onion lines showing sporadic transgene expression from approximately 1200 *A. tumefaciens*-treated cultures derived from

precultured mature zygotic embryos, and chimaeric transgenic onion plants regenerated from *A. tumefaciens*-treated organogenic structures formed on onion ovaries by Bastar *et al.* (2003). Aswath *et al.* (2006) reported the regeneration of somatic embryos from precultured seedling radicles, but did not report the number of phenotypically normal plants regenerated, and the constitutive nature of transgene expression in the putative transgenic onion plantlets developed by that group cannot be confirmed without the presence of a visual reporter gene.

To date, the most consistent method of regenerating transgenic onion plants showing constitutive transgene expression uses immature embryo-derived cultures (Eady *et al.*, 2000, 2003a; Eady, 2001a). As such, immature embryos from bulb onion cv. "CLK" extracted from seed with a recently blackened seed coat and liquid endosperm were selected for *A. tumefaciens*-mediated transformation in this research. At this stage of development, wounded, immature CLK embryos have proven to be receptive to genetic transformation and *in vitro* regeneration (Eady *et al.*, 2000). Wounding induces rapid cell division and DNA synthesis, and exposes receptive cells to *A. tumefaciens*. The addition of exogenous *vir* gene activators in the form of acetosyringone enhances the infection of nonhost onion tissue by *A. tumefaciens* (Dommissie *et al.*, 1990).

2.7.5 Ex-flasking

The transfer of onion plants from *in vitro* culture to soil in the glasshouse is highly successful. However, glasshouse conditions can significantly increase pressure from pests and diseases. Light and thermal units are also not optimal for all cultivars, making cultivation to maturity in the glasshouse, and the curing and storage of bulbs, particularly difficult. Losses due to pests and disease are difficult to prevent once such a problem has established. Problems such as these have not been resolved and are thought to be an integral part of transgenic onion cultivation in a glasshouse situation. Onions do not generally thrive in glasshouse conditions and the often compromised state of tissue culture material exacerbates the problem.

2.8 Analysis

2.8.1 Transgene detection

Initially, the presence of the transgene in putative transgenic onion tissue was screened using polymerase chain reaction (PCR) in order to amplify specific fragments of a particular transgene. For both the *bar* and *pmi* genes, we have been unable to specifically detect the presence of the transgene fragment without also obtaining very faint positive bands within nontransgenic onion samples. Despite a large difference in the degree of amplification (at least 10-fold), this uncertainty has led us to conclude that in onion, under our laboratory conditions, PCR cannot be used to conclusively demonstrate the presence of transgene fragments. However, it is routinely used to screen for CP4, *nptII*, and *m-gfpER* genes.

Currently, transformants are usually confirmed by Southern analysis (Southern, 1975) following the protocol of Eady *et al.* (2000). However, Southern analysis is expensive and time consuming. In cases of clonal propagation of a particular transgenic culture, it is necessary to confirm that all clones are derived from the same transformation event. In such a case, in which over 100 clones could easily be produced, Southern analysis would be inappropriate. For this scenario, and for the rapid easy fingerprinting of transgenic lines, our group has applied thermal asymmetric interlaced PCR (TAIL-PCR) (Liu and Whittier, 1995) to enable the detection of transgenic lines (Eady *et al.*, 2005). TAIL-PCR consists of three sequential PCR reactions using nested primers from the known inserted DNA sequence directing amplification toward the unknown flanking region, and a particular arbitrary degenerate primer to amplify back from the unknown region. We have designed TAIL-PCR specific nested primers and identified an arbitrary degenerate primer that can efficiently amplify most integrations of a pBIN19-based T-DNA in an *Allium* genome. DNA from individuals of a population of 66 plants was used as template for a TAIL-PCR, using pBIN19 right border primers Apo4RB1, 2, 3, and the arbitrary degenerate primer AD2 (Liu and Whittier, 1995). From the 67 plants, 47 (70.1%) gave results distinctive of a TAIL-PCR step-down pattern.

Sixteen different classes of product signatures were found, and in many cases, multiple plants from the same transformation plate were found to be of clonal origin. In addition, plants from the same transformation plate with different TAIL-PCR signatures were found, indicating that different transformation events could also arise from the same transformation plate.

A further benefit of TAIL-PCR over Southern analysis is that it enables sequencing of genomic DNA that flanks T-DNA inserts. Sequences of TAIL-PCR products have thus far demonstrated very precise integration at the border of the T-DNA in *Allium*. Furthermore, these sequences may be useful in identifying PCR probes for two purposes.

First, onions take 18 months to reach sexual maturity; therefore segregation analysis causes a significant delay in the route to market. The identification of homozygous individuals at the seedling stage using PCR primers will prevent this delay. Second, PCR primers to detect sequences that flank T-DNA will provide a means of cultivar identification and (presumably) ownership.

Adaptor-ligated (AL)-PCR was developed for characterizing transgenic shallots (Zheng *et al.*, 2001a). This technique is similar to TAIL-PCR in that it also enables individual T-DNA integration events, including border sequences, to be defined. The AL-PCR protocol developed by Zheng *et al.* (2001b) successfully characterized transgenic lines with multiple integration events with higher sensitivity than southern hybridizations.

2.8.2 Transgene expression and stability

2.8.2.1 Visual reporter gene expression

Mature transgenic onion, leek, and garlic plants expressing *m-gfpER* reporter gene under the control of the CaMV 35S promoter have been developed (Eady *et al.*, 2000, 2005). Microscopy examination of these transformants during regeneration under selection criteria indicated that, occasionally a line may exhibit punctate gene expression, most plants that have regenerated do express the visual reporter gene constitutively (Eady *et al.*, 2000; Kondo *et al.*, 2000; Zheng *et al.*, 2001b). The profile of CaMV 35S expression in primary transformants and first filial generations

has been determined extensively using the *m-gfpER* gene (Eady *et al.*, 2003b). The conclusions from these studies indicate that transgenes in onion, despite its large genome, are expressed in the same general way as transgenes in other species.

Twelve independent onion *m-gfpER* transformants from initial studies have been selfed and F₁ plants produced. Initial results indicate that the transgene is usually inherited in a normal Mendelian fashion and that offspring are phenotypically normal (Eady *et al.*, 2003b).

2.8.2.2 Herbicide resistance gene expression

Onion plants containing a CaMV 35S-*bar* gene construct and the constitutively expressed CP-4-derived glyphosate resistance gene have been produced. All plants that have been confirmed by Southern analysis as containing the *bar* or CP-4-derived transgenes (one or two copies) have shown a strong tolerance to the herbicides Buster[®] or Roundup[®], respectively.

Initially, a 0.5% solution of the contact herbicide Buster was painted onto the leaves of the transformed onion plants. Plants that tolerated this treatment were then sprayed with commercially recommended concentrations of Buster for general-purpose weed control to confirm resistance (Eady *et al.*, 2003a). The level of resistance achieved indicated that the commercial production of transgenic onions containing a *bar* resistance gene is a feasible option for weed control in onions.

Glyphosate-tolerant plants produced to date, which were tested in a similar manner (Eady *et al.*, 2003a), have proven to be tolerant to twice the recommended field application rates required for general weed control. F₁ seed has recently been produced from these plants and they are currently being field tested for further assessment (www.ermanz.govt.nz). It has been estimated that the deployment of glyphosate-tolerant lines in New Zealand could substitute the application of up to 151 ha⁻¹ of mainly toxic and persistent herbicides per season for approximately 4.51 ha⁻¹ of low-toxicity short-lived glyphosate, which equates to an economic saving of about US\$250 per hectare (Eady, 2001b).

2.8.2.3 Antisense alliinase gene silencing

Three sets of transgenic onion plants containing antisense *alliinase* gene constructs have recently been produced. The presence of the construct in some transgenic plants has been determined by southern blot detection of flanking T-DNA sequences (Eady, 2002b). However, the precise number of independent transgenic lines has not yet been determined, because TAIL-PCR analysis has indicated that some material that was initially thought to be clonal is actually of independent transgenic origin or from nontransgenic escape regenerants. The three sets of plants contain a CaMV 35S driven antisense root *alliinase* gene (Lancaster *et al.*, 2000); a CaMV 35S driven antisense bulb *alliinase*, initially isolated by Clark (1993); and a bulb *alliinase* promoter (Gilpin *et al.*, 1995) driven antisense bulb *alliinase*. All constructs were developed by Pither-Joyce (M.D. Pither-Joyce, personal communication). Primary transgenic material has had root and bulb tissue analyzed for alliinase level (using Western analysis) and alliinase activity (by indirect analysis of pyruvate production; Randle and Bussard, 1993). Initial results are somewhat confusing due to several compounding factors. These include the precise nature of the transgenic line, variation in the size and physiological status of the primary transformants, sensitivity of the assays, and the inefficiency of the antisense approach, which only produces an effective silencing approach in approximately 10% of transgenic lines (Smith *et al.*, 2000). It appears that the antisense root *alliinase* constructs have little or no effect on reducing root alliinase levels. Several repeated assays have now indicated that none of the antisense root lines have significantly reduced root alliinase levels compared with control plants. If the antisense technique is working, then this would suggest that the root *alliinase* sequence described by Lancaster *et al.* (2000), with only ~50% homology with the other *alliinase* sequences (Randle and Lancaster, 2002), is not in fact the source of a rate-limiting root alliinase. Results from the antisense bulb *alliinase* lines have been much more encouraging and three lines were produced with barely detectable bulb alliinase levels and activity. However, progress with this research has been confounded by the poor survival of transgenic plants.

2.8.3 Development of homozygous transgenic lines

Transgenic hybrid onion seed from these transgenic lines has been developed by crossing a nontransgenic open-pollinated parental line with a transgenic parental plant carrying a single transgene in the hemizygous state. Some resulting seed produced by the nontransgenic parents will be hemizygous for the transgene and can be selected for to give F₁ heterozygous individuals containing the transgene. Self-fertilization of these individuals produces homozygous, hemizygous, and null F₂ progeny with respect to the transgene. These homozygous individuals can then be used to generate the bulk seed required for the production of commercial transgenic lines.

3. FUTURE ROAD MAP

Methods for the transformation of important *Allium* species are still very much in their infancy and transformation efficiencies of less than 1% of starting material are still the norm. The results obtained so far suggest that the difficulties faced in obtaining transgenic Alliums lie with the effective production and selection of regeneration-competent cells that are capable of taking DNA. DNA uptake via *Agrobacterium* or bombardment can be as efficient as that observed in many other plant transformation systems. DNA integration, when it occurs and is successfully maintained, also appears no different to that obtained in other plant transformation systems. Although the technology to create transgenic Allium plants has been slow to develop, scientists are now rapidly developing further gene systems that will enable biochemists to manipulate the key enzymes involved in sulfur and carbohydrate metabolism. This will further our understanding of the role of these pathways and enable us to identify those that are important for the plant's normal physiology, and those that comprise the nutraceutical elements of these crops.

In addition, the ability to transform elite Allium cultivars will enable the introgression of traits from outside the Allium gene pool that can confer useful agronomic traits. Pest and disease resistance traits, such as those being applied to many other crops, have the potential to reduce the levels of pesticides and fossil fuels required for this crop and pave the

way for the sustainable and efficient production of Allium crops.

1. INTRODUCTION

1.1 Botanical and Genome Aspects

The genus *Asparagus*, a member of the Liliaceae, has about 150–300 species, including herbaceous perennials, shrubs, vines, ornamentals, and food species, such as *Asparagus maritimus*, *Asparagus acutifolius*, *Asparagus Pseudoscaber*, and *Asparagus officinalis* (Lawrence, 1982; Garrison and Chin, 2005). The asparagus species are distributed widely throughout the temperate and tropical regions of the world. *A. officinalis* L. is native both to the Orient and to the eastern Mediterranean, where it was cultivated by the Greeks as a vegetable crop more than 2000 years ago. *A. officinalis* is dioecious; seedlings derived from female plants generally exhibit a sex ratio of 1:1. Male plants may have both staminate and hermaphroditic flowers (Reuther, 1984). *A. officinalis* is not sexually compatible with most other *Asparagus* species. Hybrids derived from interspecific crosses have no commercial value. Female plants are homogametic XX, male plants are heterogametic XY, and hermaphroditic flowers arise on male (XY) plants due to a rare mutation. Male plants with hermaphroditic flowers (andromonoecious) can be cross- or self-fertilized (Wircke, 1979; Reuther, 1984). Andromonoecious plants produce two genotypes: XY male and YY supermale after

self-fertilizing. Andromonoecious plants can comprise 10–20% of asparagus populations (Wircke, 1979). Crossing supermales with females produces all-male hybrids, which can be desirable for production because male plants are generally more productive than female plants. The occurrence in nature of these supermales has been reported to be less than 2% (Galli *et al.*, 1998).

European diploid ($2n = 2x = 20$) (Jessop, 1966) (Figure 1) *Asparagus* species possess approximately twice the nuclear DNA of diploid southern African species (Stajner *et al.*, 2002). *A. officinalis* has been reported to have 1308 Mbp (mega base pair) (Arumuganathan and Earle, 1991) whereas asparagus fern (*A. plumosus* Baker) has 695 Mbp of DNA per 1C nucleus (Stajner *et al.*, 2002). Due to the small genome size of *Asparagus* species among members of the core Asparagales, the species may provide a useful genomic model for Asparagales (Kuhl *et al.*, 2005).

1.2 Economic Importance and Major Problems of Asparagus Production

A. officinalis is an economically important vegetable crop in over 17 countries (Reuther, 1984). In 2004, the world's top four asparagus producers were: China at 587 500 tons, followed by Peru (186 000 tons), the United States (102 780 tons),

Figure 1 The chromosomes in *A. officinalis* cv. Lucullus 234 ($2n = 20$) [Reproduced from Dan (1994)]

and Mexico (67 247 tons) (FAO, 2005). The United States produces mainly green asparagus, with a total value of production of \$140 million in 2006. Within the United States, California ranks first in production with a value of \$70.8 million, followed by Washington at \$18.9 million and Michigan at \$14.9 million in 2006 (National Agricultural Statistics Service, 2006).

Asparagus is a perennial vegetable crop, and properly maintained asparagus fields should remain profitable for 10–15 years, if adequately managed. The marketable yield, however, declines as a result of crown deaths and a reduction in the quantity and size of the spears produced (Elmer, 2001). Furthermore, “early decline” or “replant disease” can occur, if old asparagus fields are replanted with asparagus. In such cases, the replanted fields usually do not reach a profitable state (Elmer, 2001). In the late 1970s and 1980s, asparagus fields were being removed from production after only 8–15 years due to sparse stands and small spear size, resulting in low yields (Takatori and Souther, 1978). This problem is due to a disease syndrome known as “asparagus decline”, which causes loss in longevity and productivity of established fields, difficulty in replanting asparagus where asparagus was previously grown, resulting in decreased annual yield of asparagus over time. The disease occurs throughout the world (Graham, 1955; Grogan

and Kimble, 1959; Van Bakel and Kerstens, 1970; Gindrat *et al.*, 1983; Lenna *et al.*, 1985; Maurer and Maddocks, 1985; Gordon-Lennox and Gindrat, 1987; Fantino, 1990; Lenna and Foletto, 1990; Schofield, 1991; Blok and Bollen, 1995; Schreuder *et al.*, 1995; Blok and Bollen, 1996; Brayford and Uk, 1996; Elmer *et al.*, 1996; Lori *et al.*, 1998; Doan and Carris, 1999; Guerrero *et al.*, 1999; Keulder, 1999; Pontaroli and Camadro, 2001; Fiume and Fiume, 2003; Quilambaqui-Jara *et al.*, 2004; Wong and Jeffries, 2006).

Factors that contribute to asparagus decline include abiotic factors, such as environmental stress (nutrient imbalance, low soil pH and soil moisture), physical stress (defoliation by asparagus beetle, cultural practices and allelopathic substances produced by asparagus tissue), and biotic factors such as asparagus virus I and II, and *Stemphylium vesicarium* (Kitahura *et al.*, 1972; Yang, 1982, 1985; Young, 1984; Shafer and Garrison, 1986). However, the most important factors associated with “asparagus decline” are four pathogenic fungi, including *Fusarium oxysporum* f. sp. *asparagi*, *F. proliferatum*, *F. redolens*, and *F. solani* (Graham, 1955; Grogan and Kimble, 1959; Van Bakel and Kerstens, 1970; Elmer, 2001; Quilambaqui-Jara *et al.*, 2004; Wong and Jeffries, 2006). *F. oxysporum* and *F. proliferatum* are important pathogens of major crops throughout the world. They are chitinous and facultative

parasites that colonize living and nonliving host tissue and may invade nonhost tissue (Hendrix and Nielson, 1958; Alexander, 1961). They are able to form chlamydospores or other resting structures that can survive in soil for many years. These characteristics make them especially persistent once they are established (Nelson *et al.*, 1981). *F. oxysporum* causes a vascular wilt that inhibits water uptake and carbohydrate transport within the plant. *F. proliferatum* is primarily a root-rotting organism. Asparagus plants infected by either pathogen show similar above-ground symptoms; the ferns are yellowed, stunted, wilted, and may die in different stages of development. *F. oxysporum* causes root rotting and the symptoms of vascular discoloration within the stem, root, and crown whereas *F. proliferatum* causes more extensive dry crown rot and brown stem pith discoloration but no vascular discoloration (LaMondia and Elmer, 1989; Sangalang *et al.*, 1995; Elmer *et al.*, 1996, 1997).

1.3 Traditional Breeding

Andromonoecious plants of asparagus produce two genotypes: XY male and YY supermale after self-fertilizing. Crossing supermales with females produces all-male hybrids. All-male hybrids produce greater yield, are more vigorous and have greater longevity (Ellison *et al.*, 1960). In addition, increased disease resistance and drought tolerance have been associated with male plants (Ellison, 1986). YY plants are highly valued for the production of hybrid seeds, as all the progeny from crosses with female XX plants will be of the male XY constitution. Therefore, asparagus breeding programs have focused on the development of all-male hybrid cultivars with high yield, good spear quality, and enhanced resistance to asparagus rust, crown, and root rot, stem blight, and purple spot.

Asparagus breeding faces several challenges. Genetic resources of commercial asparagus cultivars are narrow (Garrison and Chin, 2005). The dioecious nature of asparagus with random mating in production fields provides limited variation in plant characters that allow for selection of breeding material. Use of interspecific hybridization is limited due to sexual incompatibilities. In addition, asparagus has a long breeding cycle.

Garrison and Chin (2005) described advances in asparagus breeding methods in several areas including: (1) selection of seed from vigorous females in production fields, (2) selection of superior male and female plants for seed production in an isolation block from which Rutgers Beacon was developed (Ellison and Kinelski, 1985), (3) division of a single desirable female and male in an isolation block to reduce heterozygosity in progeny by which F₁ cvs. Mary Washington and Martha Washington have been developed, (4) development of inbred lines through sibling crosses for several generations leading to the Limbras hybrids, and (5) breeding of andromonoecious plants (uniform male hybrids produced by selfing andromonoecious plants) (Sneep, 1953).

Tissue culture plays an important role in modern asparagus breeding and commercial seed production. One of the most significant applications of tissue culture in asparagus breeding is anther culture, which has been pioneered by Falavigna (Falavigna *et al.*, 1982, 1984a, b, 1986, 1990, 1996; Falavigna and Soressi, 1983; Falavigna and Casali, 2002). Anther/microspore culture to produce doubled haploids is an especially efficient tool for asparagus breeding. Researchers have improved the efficiency of asparagus anther/microspore culture (Wolyn and Feng, 1993; Feng and Wolyn, 1994; Ziauddin *et al.*, 1996; Peng *et al.*, 1997; Chen *et al.*, 1998; Galli *et al.*, 1998; Peng and Wolyn, 1999; Shalaby *et al.*, 2003) and developed genetic markers to identify doubled haploids for asparagus breeding programs (Restivo *et al.*, 1995; Ozaki *et al.*, 1998; Eimert *et al.*, 2003). Several important cultivars including Eros, Marte, Itala, Ercole, Zeno, and Guelph Millennium have been developed using this technology (Falavigna and Casali, 2002; Garrison and Chin, 2005). Advantages of anther/microspore culture are as follows: homozygosity obtained when haploids are doubled with colchicine; saving years of inbreeding compared to sibling crosses or andromonoecious breeding techniques; and both homozygous males and females can be obtained from superior selected male plants. Some limitations of anther/microspore culture are that not all genotypes respond to standard techniques requiring time-consuming modifications to protocols in order to obtain doubled haploids from desirable breeding material (Garrison and Chin, 2005).

The productivity of asparagus at different ploidy levels has been considered for asparagus breeding (Garrison and Chin, 2005). The questions have been as follows: is the diploid level the most productive and useful for asparagus? How are various horticultural characteristics influenced by ploidy? Triploid asparagus from crosses between $2x$ and $4x$ or $4x$ and $2x$ have exhibited low fertility. However, Hiroshima Green is a successful triploid cultivar of asparagus developed in Japan. Tetraploid asparagus has several distinctive characters compared to diploids: longer cladophylls, larger flowers, larger stomata, and larger spear diameter, as observed in cvs. Violetto, de Albenga, Purple Passion, Dulce Verde, Pacific Purple, Seto Green, and Purple asparagus.

1.4 Conventional and Alternative Strategies to Control *Fusarium*

Conventional methods of controlling *Fusarium* spp. are limited. Chemical treatments, including crown dips and foliar sprays, have not been successful (Stephens *et al.*, 1991). Fumigation does not offer long-term effectiveness because of the perennial nature of the crop (Lacy, 1979). Furthermore, *Fusarium* spp. are ubiquitous and may re-infest the soil following fumigation and rapidly colonize young asparagus plants in the field (Damicone and Manning, 1985). Cultural control, such as incorporation of cruciferous residues, reduces the *Fusarium* population, but does not eliminate the disease (Stephens and Sink, 1992). To date, no *Fusarium* resistant cultivars have been developed (Takatori and Souther, 1978; Ellison, 1986).

Alternative strategies to control *Fusarium* include the following areas. The most successful strategy for *Fusarium* wilt control in other vegetable crops has been the development of resistant cultivars (Mace *et al.*, 1981). Possibilities exist for developing *Fusarium* resistant cultivars in asparagus. A cultivar of *A. officinalis*, Lucullus 234, had the highest resistance to virulent Michigan isolates FOA10 of *F. oxysporum* and FM12 of *F. proliferatum* among 90 cultivars and breeding lines of this species tested (Stephens *et al.*, 1989). Two ornamental cultivars (Sprengeri and Myersii) of *Asparagus densiflorus* (Kunth) Jessop were resistant to *F. oxysporum* and *F.*

proliferatum in greenhouse studies (Stephens *et al.*, 1989). Furthermore, Lewis and Shoemaker (1964) suggested that *A. densiflorus* cv. Sprengeri was immune to *F. oxysporum* f. *asparagi* in a laboratory study. However, sexual crosses of *A. officinalis* with the resistant species, *A. densiflorus* "Sprengeri" were unsuccessful, probably due to incompatibility barriers (Elmer *et al.*, 1989). In addition, by conventional methods, *A. officinalis* has low regenerative potential (Reuther, 1984) and the development of new cultivars requires many years because of perennial nature of the crop. It is likely that genetic diversity among the asparagus cultivars in North America is low (Gleason and Cronquist, 1963; Luzny, 1979; Ellison, 1986). Efficient plant regeneration systems have been developed from callus-derived protoplasts of different cultivars of *A. officinalis* L. (Figure 2) (Elmer *et al.*, 1989; Dan and Stephens, 1991). In this context, protoplast fusion technology can be an alternative to produce somatic hybrids between *A. officinalis* L. cv. Lucullus 234 and *A. densiflorus* cv. Sprengeri, which could be resistant to *F. oxysporum* f. *asparagi*.

Somaclonal variation has been used to recover genetic variability in several crops and offers an alternative to mutation breeding (Veilleux and Johnson, 1998). Two asparagus somaclonal lines with high levels of resistance to *Fusarium oxysporum* f. sp. *asparagi* have been developed from selection of plants regenerated from protoplasts of "Lucullus 234" in response to *F. oxysporum* and *F. proliferatum* (Dan and Stephens, 1995). In addition, no morphological or growth differences were observed between these lines and the parental cultivar. Later, Dan and Stephens (1997) reported that the two resistant somaclonal lines, which demonstrated higher levels of resistance to *Fusarium oxysporum* f. sp. *asparagi*, carried numerous DNA sequence variations different from the parental source, identified by random amplified polymorphic DNA (RAPD). The DNA sequence variation indicated possible mutations derived from tissue culture in the two lines. In a study of plants derived from embryogenic calli of asparagus, Kunitake *et al.* (1998) reported an increase in chromosomal variation among the regenerated plants with increasing duration of culture, particularly when haploid and diploid clones were the source of explants. In studies of molecular marker analysis

Figure 2 Development of *A. officinalis* cv. Lucullus 234 from callus-derived protoplasts to plants (a–f). (a) Asparagus protoplasts immediately after isolation from calli; (b) first division of protoplasts embedded in agarose of bead culture, 1 day after isolation; (c) a colony of about 10 cells derived from protoplasts embedded in agarose of bead culture 5 days after isolation; (d) microcalli derived from protoplasts embedded in agarose of bead culture 2 weeks after isolation; (e) calli derived from protoplasts on shoot-inducing medium, 1 week after initiation of bead culture; and (f) regeneration of shoots and plantlets from protoplasts-derived calli in hormone-free medium [Reproduced from Dan (1994)]

of regenerated asparagus plants, Raimondi *et al.* (2001) found that RAPD markers did not differentiate obviously different somaclones from controls; however, Pontaroli and Camadro (2005) reported differences in nearly 3% of amplified fragment length polymorphism (AFLP) markers between asparagus derived from long-term callus cultures and the control cultivars. The greater genome coverage of AFLPs and the longer duration of the callus cultures to accumulated genomic changes in the somaclones may underlie the differences between the studies.

The soil bacterium, *Agrobacterium tumefaciens*, can infect most dicotyledonous plants at wounding sites (Gelvin, 2003) and induce formation of tumors, called crown gall, via transfer of its Ti plasmid (Van Larebeke *et al.*, 1974; Zaenen *et al.*, 1974; Watson *et al.*, 1975). When the bacterium comes in contact with a wounded plant cell, the Ti-plasmid is transferred from the bacterium into the cell. A small segment of the plasmid, transfer DNA (T-DNA), is transferred from the plasmid to the nucleus of the plant cell, and becomes integrated into the plant nuclear genome

(Chilton *et al.*, 1977, 1978; Willmitzer *et al.*, 1980). *Agrobacterium*-mediated gene transfer has become a powerful tool for introducing foreign genes into many plant species to improve agricultural crops such as virus resistant potato and papaya (Gonsalves, 2004; Schubert, 2006) and increasing resistance to pathogenic viruses (Nelson *et al.*, 1988; Hoekema *et al.*, 1989; Fuentes *et al.*, 2006; Furutani *et al.*, 2006; Zhang *et al.*, 2006; Zhao and Zhao, 2006), fungi (Broglie *et al.*, 1991; Kanzaki *et al.*, 2004; Lin *et al.*, 2004; Pei *et al.*, 2005; Salehi *et al.*, 2005), and bacteria (Destefano-Beltran *et al.*, 1990; Datta, 2004; Lin *et al.*, 2004). Originally *Agrobacterium*-mediated transformation was expected to be limited to dicotyledonous plant species that the bacterium naturally infects; however, it was subsequently learned that *Agrobacterium* can transfer its T-DNA to cells of nonhost monocotyledonous plants such as asparagus (Hernalsteens *et al.*, 1984; Bytebier *et al.*, 1987; Delbreil *et al.*, 1993; Limanton-Grevet and Jullien, 2001), rice, wheat, corn, barley, sorghum and forage grasses (Graves and Goldman, 1986; Raineri *et al.*, 1990; Mooney *et al.*, 1991; Cheng *et al.*, 2004). Therefore, genes for resistance to *Fusarium* (Pei *et al.*, 2005) can now be introduced into *Asparagus* via *Agrobacterium*-mediated or biolistic transformation.

2. DEVELOPMENT OF TRANSGENICS

2.1 Asparagus Transformation

Asparagus was one of the first monocots for which regeneration of plants transformed by *A. tumefaciens* was reported (Bytebier *et al.*, 1987). In this study, spears of *in vivo* asparagus were surface sterilized, placed on half-strength MS (Murashige and Skoog, 1962) medium and inoculated with *A. tumefaciens* strain C58C1. Three calli, two of which regenerated plants, tested positive for the T-DNA that carried nopaline synthase and kanamycin resistance. Delbreil *et al.* (1993) improved upon the technique by inoculating embryogenic asparagus callus with *A. tumefaciens* carrying β -glucuronidase (*uidA*) and neomycin phosphotransferase II (*nptII*) genes and regenerated a plant that exhibited T-DNA integration. A more extensive analysis of T-DNA

integration into plants regenerated from embryogenic lines of asparagus that had been inoculated with *A. tumefaciens* strain AGL1Gin carrying a *uidA* gene and an *nptII* gene was conducted by Limanton-Grevet and Jullien (2001). Their transformation frequency ranged from 0.8 to 12.8 transformed plants per gram of inoculated somatic embryos. The T-DNA copy number per transformant ranged from one (in eight lines) to many among the 24 lines analyzed. The higher transformation rate was attributed to the more virulent strain of *Agrobacterium* used. Mendelian segregation of the transgene was observed after three of the six transformed plants were testcrossed to a nontransgenic to generate T₁.

An alternative to *Agrobacterium*-mediated transformation that has been used especially for monocots is the biolistic gun, also called the gene gun or particle bombardment. Three studies have been published on asparagus transformed using particle bombardment (Cabrera-Ponce *et al.*, 1997; Li and Wolyn, 1997; Shigemoto and Kohmura, 2002). Shigemoto and Kohmura (2002) reported that four transgenic asparagus plants were obtained from embryogenic cells by particle bombardment using a hygromycin phosphotransferase (*hpt*) gene and, in these plantlets, integration of *hpt* gene was confirmed by polymerase chain reaction (PCR) analysis. Li and Wolyn (1997) used tungsten particles coated with the pKGUS plasmid carrying the *nptII* and *uidA* genes. They obtained 10 transgenic plants derived from suspension culture of asparagus but they all revealed the same southern hybridization pattern, implying that they all derived from the same transformation event. The plasmid DNA appeared to have integrated into the asparagus genome as head-to-tail concatemers. The third particle bombardment report on asparagus was conducted with a plasmid carrying *hpt*, *gus*, and *pGPTV-Bar* (bialaphos resistance). Somatic embryo cultures of asparagus were bombarded followed by regeneration of transformed asparagus plants by secondary embryogenesis. The transformants varied for the number of integrated copies of the *nos-bar* and CaMV 35S-*hpt* genes present in the genome. However, five lines exhibited resistance to the herbicide phosphinothricin compared to the sensitive control plants.

In addition to *Agrobacterium*-mediated and biolistic transformation, there is a single report

of electroporation of asparagus protoplasts with plasmid DNA containing *nptII* and *gus* (Mukhopadhyay *et al.*, 2002). Callus-derived protoplasts were used as targets of transformation. The integration of foreign DNA into the genome of regenerated plants was confirmed by Southern blot analysis.

2.2 Selection of Transformed Tissue

As described above, three sources of antibiotic resistance genes, including *nptII* (Delbreil *et al.*, 1993; Li and Wolyn, 1997; Limanton-Grevet and Jullien, 2001), *hpt* (Cabrera-Ponce *et al.*, 1997; Shigemoto and Kohmura, 2002), and phosphinothricin-*N*-acetyltransferase (*pat*) (Cabrera-Ponce *et al.*, 1997) have been used for selection of transgenic asparagus. With *nptII*, selection for transformed plant material has been conducted using kanamycin in the range of 50–100 mg l⁻¹. For hygromycin selection after transformation with constructs carrying the *hpt* gene, 25–100 mg l⁻¹ were used during culture of embryogenic callus. In addition, herbicide resistance (*pat* gene) has been used to select transformed embryos after biolistic transformation.

2.3 Selection of Whole Plants

Despite the wealth of literature describing transformation of asparagus by any of the three different methods using a range of tissue types and strains of *A. tumefaciens*, there has been no attempt to introduce a gene of interest that would improve asparagus cultivation or quality. Only selectable markers and reporter genes have been introduced thus far into asparagus transformants. There is only a single mention of field tests of transformed asparagus, in New Zealand (Christey and Woodfield, 2001). In this study, the transgenic trait was listed as marker and reporter genes.

3. FUTURE ROAD MAP

3.1 Expected Products

Important traits such as herbicide tolerance, insect resistance including the *Bt* gene for control

of beetles and disease resistance genes for important asparagus diseases can be introduced transgenically into asparagus to enhance breeding programs. Breeding targets for increasing nutritional compounds in asparagus to improve its human health benefit include: the flavonoid rutin, an antioxidant that may reduce serum cholesterol; and anticarcinogens such as protodioscin (a steroid saponin) that inhibited cancer cell growth, decreased cholesterol in plasma and liver, and enhanced sexual activity (Garrison and Chin, 2005).

3.2 Expected Technologies

Plant transformation via *Agrobacterium* has significantly advanced from dicots to monocots in approximately last 20 years. Today agricultural biotechnology is heavily dependent on using *Agrobacterium* to produce transgenic plants. Technology to improve asparagus transformation efficiency can be advanced through studying: (1) transformation cell biology such as plant regeneration pathways, enhancement of *Agrobacterium* infection of explants and prevention of necrosis of transformed cells/tissues, (2) molecular biology, including identification of plant genes encoding proteins that interact with *Agrobacterium* virulence proteins, forward genetic screening to identify plant genes involved in *Agrobacterium*-mediated transformation, and reverse genetic screening for plant genes involved in *Agrobacterium*-mediated transformation (Gelvin, 2003), and (3) genomics approaches to identify plant genes that respond to *Agrobacterium* infection (Gelvin, 2003) and understand the mechanisms of *Agrobacterium*-induced necrosis and the role of antioxidants in plant transformation.

Identifying transformants that have successfully incorporated transgenes of interest, termed as transformation selection, is required for developing an efficient transformation method. Determining appropriate selective agents for asparagus under different culture conditions is critical to select and identify transformants. Despite approximately 50 selective marker genes that could be used for plant transformation (Miki and McHugh, 2004), only three selective marker genes, including *nptII*, *hpt*, and *pat*, have been used for *Asparagus* transformation. Many of the selective genes for plant transformation, which

have not been tested before, may be more effective in *Asparagus* transformation. Inserting introns into the coding region of *hpt* (Wang *et al.*, 1997) as its enhancing transgene expression in monocot species (Simpson and Filipowicz, 1996) can be an alternative strategy to improve selectable marker genes for asparagus transformation. The introduction of introns into *hpt* not only improved transformation frequency in *Agrobacterium*-mediated transformation of rice due to elevated *hpt* expression but also reduced copy numbers of the marker gene. In addition, inserting the introns into the marker gene also enabled better control of *Agrobacterium* growth during the transformation process (Wang *et al.*, 1997). This strategy also enhanced stable transformation with elite rice and barley cultivars as well (Upadhyaya *et al.*, 2000; Wang *et al.*, 2001). Promoters that have been identified in rice, corn, and wheat and showed increased transformation efficiency may be applied to asparagus transformation (Last *et al.*, 1991; Rasco-Gaunt *et al.*, 2003; Meyer *et al.*, 2004).

New cloning technology and vector design technology, recombinase-mediated auto-excision of transgenes directed by a tightly controlled microspore-specific promoter, allows efficient removal of either the selectable marker gene or of all introduced transgenes during microsporogenesis (Mlynárová *et al.*, 2006). This technology, which removes transgene via an integral part of the biology of pollen maturation, not requires any external stimulus such as chemical induction by spraying. This technology can open the door for advancing genetically modified (GM) crop development technology regarding public concern of the spread of antibiotic resistance.

1. INTRODUCTION

Leafy vegetables, consumed in the cooked or raw state, form an essential component of a well-balanced diet. Traditionally, lettuce has been an important leafy vegetable, being grown extensively as a salad crop worldwide and consumed primarily in the fresh state. Other leafy vegetables, such as chicory or spinach, are eaten both fresh and cooked. Currently, young leaves of leafy vegetables are becoming popular components of “baby salad” packs. Indeed, it is likely that the range of leafy vegetables will expand in the immediate future. This review focuses on lettuce, chicory, and spinach; other crops are mentioned briefly, as appropriate.

1.1 Origin, Distribution, and Economics of Production of Leafy Vegetables

1.1.1 Lettuce

Lettuce (*Lactuca sativa* L.), is a self-fertile, annual species of the family Asteraceae, with a chromosome complement of $2n = 2x = 18$. Seven morphological types of lettuce exist, namely (i) Crisphead, Iceberg or Cabbage, (ii) Butterhead, (iii) Cos, (iv) Leaf or Cutting, (v) Latin, (vi) Stem or Asparagus, and (vii) the Oilseed group (Ryder, 1999). Crisphead varieties have compact, large heads whilst Butterhead types have crumpled, soft-

textured leaves. Cos types are characterized by long, oval, dark upright green leaves, forming oblong heads or hearts. Leaf types, as the name implies, produce a rosette of loose leaves; Latin cultivars (cvs.) are intermediate between the Butterhead and Cos types in forming loose heads with oval leaves. In stem-type cultivars, the young fleshy stems are eaten after being cooked. Oil-seed-type lettuces bolt rapidly and are probably primitive forms of *L. sativa*. Lettuce is classified on its leaf shape and size, rather than pigmentation (Ryder, 1999).

The geographical origin of lettuce is uncertain, but it may be Egypt, the Mediterranean region, the Middle East, and South West Asia. Lettuce cultivation in Europe dates from the late 1400s, followed by introduction of the plant into America, with the selection of Crisphead cvs. (de Vries, 1997). Kesseli *et al.* (1991) suggested a polyphyletic origin for *L. sativa* based on variation from restriction fragment length polymorphism (RFLP) analysis of 67 accessions of *L. sativa* and 5 other *Lactuca* species. Frijters *et al.* (1997) in attempting to advance understanding of the lettuce genome, constructed a bacterial artificial chromosome (BAC) library containing large *Eco*R1 and *Hind*III genomic fragments, while Waycott *et al.* (1999) mapped genes for morphology to molecular markers. Subsequently, Johnson *et al.* (2000) reported a molecular comparison of cultivated lettuce with its wild progenitor, *Lactuca serriola*, while Dziechciarková

et al. (2004) exploited protein and molecular marker technologies to elucidate aspects of the taxonomy, biodiversity, genetics, and breeding in *Lactuca*.

The market for lettuce has expanded in the last decade, with more varieties being cultivated in line with consumer requirements for novel produce. The annual production of lettuce in the United States is about 4 million tons, valued at \$1.6 billion (United States Department of Agriculture, 1998), in excess of 2 billion heads being harvested annually. Seventy percent of US production is in the field in California (Pink and Keane, 1993). Other regions of cultivation are Canada, Northern Europe, and Mexico, South America, South Africa, the Middle East, Japan, China, and South-East Australia. Globally, 19 million tons were produced in 2002 (FAOSTAT, 2003). Lettuce ranks about 26th in comparison to other fruits and vegetables in terms of its contribution to the human diet, following tomato and orange with respect to bulk consumption in the United States.

1.1.2 Chicory

Chicory (*Chicorium intybus*) is also a member of the Asteraceae. Phenotypically, this biennial monoecious plant occurs as rosette, Witloof, and heading types. The former are open in habit with elongated and either divided or entire leaves; heading varieties produce green, variegated or red leaves, with heads of different morphology. Witloof chicory is produced by growing roots of 1-year-old plants of the rosette type in the dark in either sand or hydroponic culture to produce white buds (chicons). The latter are cooked as a luxury vegetable.

1.1.3 Spinach

Spinach (*Spinacia oleracea*), in the family Chenopodiaceae, is cultivated as an annual for its leaves and as a biennial for seed. Its growth habit is similar to that of lettuce and chicory with the fleshy, upright, wrinkled (savory), or smooth leaves forming a compact rosette. Flowering is initiated by temperature and photoperiod (Correll *et al.*, 1994). Spinach prefers cool climates and tolerates

frost better than most other leafy vegetables (Goto *et al.*, 1999a). Spinach is consumed both fresh and after processing (canned and frozen), with approximately 87 000 tons being processed during 1999 in the United States. The concentrations of dietary minerals and vitamins are typically high (Goto *et al.*, 1996) with about 93 mg of calcium and 51 mg of vitamin C in 100 g fresh weight of leaves, together with iron, phosphorus, and sodium (Ryder, 1999).

1.2 Genetic Improvement of Leafy Vegetables by Traditional Breeding

As in all crop plants, there is a continual requirement to genetically improve leafy vegetables to increase their resistance to insects, diseases, abiotic and biotic stresses. Yield and nutritional value are also important targets for genetic manipulation using conventional breeding and somatic cell technologies.

1.2.1 Lettuce

More effort has been invested in the genetic improvement of lettuce than other leafy vegetables by conventional breeding, probably reflecting consumer demands. Breeding objectives for cultivated lettuce include modifying leaf shape and color, manipulating head formation, delaying bolting, and the introduction of male sterility and resistance to insects, herbicides, and diseases. The latter include downy mildew and Lettuce Mosaic Virus (LMV) (Ryder, 2002), *Fusarium* wilt (Garibaldi *et al.*, 2004), root rot (Tsuchiya *et al.*, 2004), and corky root disease (Dufresne *et al.*, 2004; Mou and Bull, 2004). Resistance to dieback (Grube and Ryder, 2003; Grube *et al.*, 2005), *Sclerotinia minor* (Grube and Ryder, 2004), and *Bremia lactucae* (Jeuken and Lindhout, 2002; Lebeda and Petrželová, 2004) also represent key targets of conventional breeding. Improved leaf quality and succulence, with a decrease in latex and bitter taste, reduced nitrate accumulation under glass, and extended shelf life following harvest (de Vries, 1997), are relevant to this crop.

Self-fertilization is efficient in lettuce, although cross hybridization is possible. Pedigree breeding,

selection breeding, and back crossing are the principal methods of lettuce improvement (Ryder, 1999). *L. sativa* is sexually compatible with only a limited number of members of the genus, particularly *Lactuca saligna*, *L. serriola*, and *Lactuca virosa*. Important traits that have been introgressed from *L. virosa* into *L. sativa* include resistance to LMV, decreased susceptibility to tipburn, reduced bitterness, and a more extensive root system. Other useful traits include resistances to downy mildew and LMV from *L. serriola*, leaf aphid (*L. virosa*), and cabbage lopper (*L. saligna*; de Vries, 1990). An emphasis of breeding programs has been to identify and to introduce novel genes for resistance to viruses and fungi (Witsenboer *et al.*, 1995). The fungal pathogen *B. lactucae*, which is prevalent in the cool wet climate of Northern Europe, is the cause of downy mildew, the most destructive fungal disease of lettuce. Most lettuce breeding programs incorporate mildew resistance. LMV, transmitted by aphids, is the most destructive viral disease of lettuce (Revers *et al.*, 1997), with aphids and whitefly acting as viral vectors. Jeuken and Lindhout (2004) developed backcross inbred lines (BILs) in which chromosome segments from the wild species, *L. saligna*, were introgressed into *L. sativa*, through four to five backcrosses and one generation of selfing, with marker-assisted selection commencing in the fourth backcross generation. BIL association mapping enabled the location to be determined of 12 morphological traits and amplified fragment length polymorphism (AFLP) markers. Such BILs will be essential in future genetic studies in *Lactuca*.

Product quality is important, particularly uniformity of size, yield, postharvest shelf life, and nitrate content. Accumulation of nitrate in lettuce and other vegetables is undesirable, since in humans nitrate produces nitrite that hinders the binding of oxygen to hemoglobin. Nitrite also generates carcinogenic nitrosamines that may cause gastric cancers (Gunes *et al.*, 1995). As lettuce is generally consumed raw, there is a need to limit nitrate concentration in this crop (Gaudreau *et al.*, 1995; Santamaria, 1997). Year-round cropping, uniformity of size and time to maturity are primary commercial targets. Quality and appearance govern saleability; prolonged postharvest shelf life is equally important because of the rapid decay of the crop.

Molecular marker technologies will facilitate breeding programs with identification of genes and markers, resulting in the development of a genetic map for lettuce. Ninety or more genes in lettuce encode for leaf and floral morphologies and pigmentation, disease and insect resistances, seed and fertility and plant development (Ryder, 1999). Kesseli *et al.* (1994) constructed a genetic map using isozyme, RFLP, and random amplified polymorphic DNA (RAPD) analyses. Other morphological traits were mapped in lettuce relative to RAPD markers (Waycott *et al.*, 1999). Traits for morphological characteristics such as dwarf phenotype, white seed, brown seed, salmon flower color, pale yellow flower color, virescent juvenile leaf color, plump involucre, yellow seed, and anthocyanin spotting were linked to RAPD loci. Pigmentation and form is diverse in lettuce (Ryder, 1999; Ryder *et al.*, 1999) with several of the forms being characterized genetically. Ryder (1999) reviewed progress in identifying genes that govern disease resistance and morphological characteristics, while Waycott *et al.* (1995) studied the genetic control of plant stature in lettuce.

A BAC library was also constructed containing large *EcoRI* and *HindIII* genomic fragments of lettuce (Frijters *et al.*, 1997) and screened with markers linked to disease resistance genes. Additionally, quantitative trait loci (QTL) were identified for differences between wild and cultivated lettuce with respect to root architecture (Johnson *et al.*, 2000). Undoubtedly, continued expansion of the genetic map for lettuce will facilitate the identification of agronomically useful genes for introduction into this crop.

1.2.2 Chicory

Chicory is monoecious with sexual hybridization being hampered by the biennial life cycle, the sporophytic self-incompatibility of many cultivars (Ryder, 1999), and the difficulty in synchronizing bolting of different genotypes (Varotto *et al.*, 2000). Flowering occurs following vernalization at 8–18 °C when day length exceeds 13 h during the second season of growth. Several traits are targets for both conventional breeding and genetic manipulation technologies. Chicory roots contain up to 20% stored carbohydrates (Frulleux *et al.*, 1997), which, upon hydrolysis, yield 18% fructose

and 2% sucrose, which are of industrial interest. Genetic improvement of cultivars grown for their roots may result in plants with enhanced fructose production and increased commercial value. One of the stored carbohydrates, inulin, is a probiotic of bifidiobacteria present in the human gut, where it is thought that bacteria convert inulin to compounds that display anticarcinogenic activity (Vijn and Smeekens, 1999). Roots of chicory provide a coffee substitute (Bais *et al.*, 2001). Since seedling growth in the field is slow, resulting in weeds out-competing the crop, resistance to nonselective herbicides is a key target for crop improvement. The production of high quality chicons is also important commercially. Indeed, during forcing, both the taproot and chicons of Witloof chicory are susceptible to bacterial and fungal infections (Chupeau, 1989), making resistance to pathogens additional targets for genetic improvement. As in lettuce, nitrogen metabolism is a target for crop improvement (Abid *et al.*, 1995).

1.2.3 Spinach

Spinach is dioecious making traditional breeding difficult, although monoecious individuals do occur. Flowers of both male and female plants are formed in clusters of 6–12 and develop sequentially. Female flowers have a single ovary. Sex is influenced by X and Y chromosomes (Panday and Kalloo, 1986), as well as environmental factors including light, temperature, and growth regulators (Chaliakhyan and Khyranin, 1978). Application of gibberellic acid (GA₃) increased the percentage of male plants to 79%, while treatment with benzylaminopurine (BAP), indole acetic acid (IAA), and abscisic acid (ABA) increased the percentage of female plants. Targets for spinach breeders include nutritional quality, tolerance to elevated temperature and acid soils, resistance to viral and fungal diseases, and a reduction in oxalate concentrations, since the latter interferes with Ca²⁺ uptake in humans (Goto *et al.*, 1996).

2. TISSUE CULTURE OF LEAFY VEGETABLES AS A BASIS FOR GENETIC MANIPULATION

Tissue culture-based technologies involving micropropagation, *in vitro* pollination, anther and

ovule culture, embryo rescue, exposure of somaclonal variation, somatic hybridization and transformation, are approaches that complement conventional plant breeding. Reproducible tissue culture-based procedures for the regeneration of fertile plants from cultured explants, cells, and isolated protoplasts, are fundamental to the exploitation of these technologies. Importantly, several *Lactuca* species, including *L. sativa*, chicory, and spinach, are amenable to culture in the laboratory, with shoot regeneration from cultured cells. Additionally, protoplasts of lettuce are totipotent. In general, tissue culture of spinach is more difficult than that of lettuce or chicory.

2.1 Lettuce

2.1.1 Embryo rescue and organogenesis

Shoot tips were cultured in order to micropropagate F₁ hybrid lettuce plants (Takano *et al.*, 1988), while embryo rescue permitted the recovery of sexual hybrids between *L. sativa* and *L. virosa* (Maisonneuve *et al.*, 1995). The response of explants, such as seedling hypocotyls, to the components of growth media, particularly growth regulators, in terms of adventitious bud initiation, was discussed by Michelmore and Eash (1988) and Xinrun and Conner (1992). Ampomah-Dwamena *et al.* (1997) screened 22 lettuce genotypes of different morphological groups for their shoot regeneration response on Schenk and Hildebrandt (SH; 1972) medium containing 3% (w/v) sucrose, 0.1 mg l⁻¹ IAA, 0.5 mg l⁻¹ kinetin, and 0.05 mg l⁻¹ zeatin. Reproducible shoot regeneration was recorded from Crisphead-, Butterhead-, Leaf- and Cos-type lettuce varieties. In general, regeneration was achieved using a medium with the Murashige and Skoog (MS; 1962) formulation with 3% (w/v) sucrose, 0.04 mg l⁻¹ α -naphthalene acetic acid (NAA), 0.5 mg l⁻¹ BAP (benzyladenine, BA), and semi-solidified with 0.8% (w/v) agar at pH 5.8. An incubation temperature of 23 \pm 2 °C with a 16 h photoperiod (18 μ mol m⁻² s⁻¹, daylight fluorescent tubes) was satisfactory. Marked differences occur in callus initiation and shoot regeneration from different cultivars, while hyperhydricity may impair shoot regeneration in some cvs. Investigations of plant regeneration from suspension cultured cells exploited batch cultures, although Teng *et al.*

(1993) studied regeneration from cells cultured in 21 bioreactors. These authors focused on several parameters, including the effects of foaming, aeration, and “wall effects” of the culture vessels. Aeration through a screen column with 150 μm pores, prevented foaming, removed the wall effect, and maximized shoot regeneration.

Frequently, seedling cotyledons have been the source of explants because of their uniformity and their rapid shoot regeneration response (Webb *et al.*, 1984). Regeneration normally proceeds by organogenesis, although Zhou *et al.* (1992) reported somatic embryogenesis from cotyledons on MS-based medium with either 2.0 mg l^{-1} BA and 0.2 mg l^{-1} NAA, or 0.2 mg l^{-1} BA with 2.0 mg l^{-1} NAA. More recently, Hunter and Burritt (2004) studied the effects of light on organogenesis from cotyledons of the cvs. Bambino, Greenway, Red Coral, and Red Oak Leaf. These authors suggested that phytochrome, cryptochrome, and blue light influence shoot regeneration from lettuce cotyledons.

2.1.2 Somaclonal variation in lettuce

Somaclonal variation, usually observed as morphological differences between individuals, is relatively common in plants regenerated from cultured cells and tissues. However, the precise mechanisms involved are still not clear (Kaeppeler *et al.*, 2000). Changes in chromosome complement, structure, and DNA sequence have been observed (Choi *et al.*, 2000). Somaclonal variation is probably related to several factors, such as increased DNA methylation following the “shock” of introducing tissues into culture, chromosome breakage and rearrangement (Jain, 2001), interference with the normal cell cycle, and amplification of repetitive DNA sequences (Gyulai *et al.*, 2003). Activation of transposable elements (Jain, 2001) and changes induced by growth regulators, especially 2,4-dichlorophenoxyacetic acid (2,4-D) (Arun *et al.*, 2003) may influence such variation. Tissues from differentiated organs, such as stems, leaves, and roots, often produce plants with more variation than explants with pre-existing meristems, such as shoot tips and axillary buds (Sahijram *et al.*, 2003). In addition to phenotypic analyses, molecular techniques such as RFLP markers, polymerase chain reaction (PCR)-based RAPD and AFLP technologies (Polanco and Ruiz, 2002), have been

developed to study somaclonal variation in tissue culture-derived plants (Rahman and Rajora, 2001; Sahijram *et al.*, 2003).

Somaclonal variation in lettuce has been exposed following culture of tissues and isolated protoplasts (Brown *et al.*, 1986). Such variation included increased vigor and early flowering habit, increased chlorophyll, and reduced susceptibility to both LMV and *B. lactucae*. Somaclonal variants were also observed during the establishment of protoplast-to-plant systems for lettuce, as discussed later. Protoplast-derived variants also exhibited variation in pigmentation, with elongated and wrinkled leaves, dwarfism and increased vigor. However, most of the somaclonal variants of lettuce have shown some deleterious characteristics, such as reduced fertility. Despite these negative effects, somaclonal variation may expose genetically stable, agronomically useful characteristics and any variant plants arising from culture are worthy of evaluation.

2.2 Chicory

2.2.1 *In vitro* pollination, microspore culture, embryo rescue, and organogenesis

Six cultivars of chicory, including the cv. Chioggia, have been pollinated *in vitro* with pollen from *Lactuca tatarica* and *Cicerbita alpina* (Doré *et al.*, 1996). The most embryos resulted following pollination by *C. alpina*. However, only the cv. 449-2 produced embryos and plants when crossed with *L. tatarica*, two plants being obtained from 55 capitulae. The generation of haploid plants or hybrids was dependent on the cv., with the cv. BO9 producing hybrids and cv. FD1-12 producing haploid plants.

Ovule pollination has been employed in chicory to overcome self-incompatibility (Castaño and De Proft, 2000). Ovules isolated from flower heads and buds of the cvs. Flash and Carolus were cultured on media based on the MS or B5 (Gamborg *et al.*, 1968) formulations with 4–6% (w/v) sucrose. Culture of pollinated ovules at 22 °C with a 16 h photoperiod produced some seedlings. The optimum response was in the cv. Carolus on MS medium with 7.5 mg l^{-1} glycine, 0.5 mg l^{-1} IAA, 0.5 mg l^{-1} kinetin, and 4 mg l^{-1} GA₃.

Chromosome analyses showed the plants to be diploid, as expected.

Unfortunately, anther and ovule culture, together with pollen irradiation and ovule irradiation, have been unsuccessful in generating haploid plants in chicory. However, success has been obtained through microspore culture (Theilerhedtrich and Hunter, 1995). Uninucleate microspores were cultured on MS-based medium supplemented with 0.5 mg l^{-1} 2,4-D, 0.5 mg l^{-1} IAA, and 2 mg l^{-1} zeatin for up to 6 months to induce callus. The latter was subcultured on medium containing 0.5 mg l^{-1} BAP and 0.5 mg l^{-1} IAA; shoots were induced by decreasing the inorganic components in the presence of 0.4 mg l^{-1} kinetin and 0.2 mg l^{-1} IAA. Adventitious roots developed on the regenerated shoots in half-strength Quoirin and Lepoivre (1977) medium with 0.2 mg l^{-1} indole butyric acid (IBA). Forty-four of 450 regenerated plants were haploids.

Varotto *et al.* (2000) used embryo rescue to regenerate plants from zygotic embryos of the cv. Rosso di Chioggia. Plants were hand pollinated with pollen from five different genotypes in order to overcome self-incompatibility. Embryos at the heart or torpedo stages 72 h after pollination, cultured on semi-solid B5 medium with Morel and Wetmore's (1951) vitamins, 800 mg l^{-1} glutamine and 1% sucrose, with a 14 h photoperiod at 25°C , produced green plants within 2 weeks of culture. Younger embryos failed to develop or produced abnormal plants. Culture of zygotic embryos may reduce the duration of breeding programs, since it circumvents embryo abortion.

Cells of chicory, like those of lettuce, are totipotent (Frulleux *et al.*, 1997) enabling plants to be regenerated by organogenesis and somatic embryogenesis from cultured tissues. Mix (1985) regenerated fertile plants of spinach by culturing vein explants from unexpanded leaves on MS-based medium. The shoot regeneration response varied between cvs. In the same year, Bennici and Riepma (1985) demonstrated that storage roots of the cv. Cicoria Dolce de Soncino regenerated shoots on agar-solidified medium. Such shoots, when excised, developed roots on transfer to MS-based medium supplemented with IBA, permitting the recovery of intact, fertile plants.

Early in the 1990s, leaf explants of the cv. Witloof produced nodular tissues on the medium of Quoirin and Lepoivre (1977), with BAP and

IBA as the growth regulators (Pieron *et al.*, 1993). Tissues were transferred to medium lacking growth regulators to stimulate bud formation followed by shoot development. Tissues developed in contact with the vascular bundles of the leaves (Pieron *et al.*, 1998), vascular centers within these tissues being the sites of bud initiation. Adventitious buds were also initiated from leaf explants excised from the cv. 474, a sexual hybrid between *C. intybus* and *C. endivia* (Decout *et al.*, 1994). Shoot formation was optimum at 25°C , with wounding being essential for morphogenesis. An interesting observation of possible application to chicory breeding, was that addition to the culture medium of silver nitrate or putrescine, both at 40 mM, initiated flowering of regenerated shoots within 28 days of the introduction of explants into culture (Bais *et al.*, 2001). Later, Rehman *et al.* (2003) improved the efficiency of shoot regeneration from leaf explants of Witloof chicory using MS-based medium with IAA, kinetin, and casein hydrolysate, followed by rooting on medium with IBA. Plants regenerated from leaf explants accumulated more esculin than plants grown *in vivo*. The ability to regenerate plants by organogenesis, from cultured leaf explants, seedling cotyledons, and shoot buds provided a basis for the subsequent generation of transgenic plants in this leafy vegetable (Vermeulen *et al.*, 1992; Abid *et al.*, 1995; Frulleux *et al.*, 1997).

2.2.2 Somatic embryogenesis in chicory

Plants can also be regenerated by somatic embryogenesis in chicory, as in the cv. Witloof (Heirwegh *et al.*, 1985). Dubois *et al.* (1988), while investigating androgenesis in chicory, reported the formation of somatic embryos from the sporophytic regions of cultured anthers. Styles from the cv. 474 were cultured on semi-solid, half-strength, MS-based medium, in which KNO_3 of the original formulation was replaced with 10.1 mM KCl and 1.7 mM glutamine, with the inclusion of the microelements of Heller (1953), 5×10^{-3} Fe-EDTA, Morel and Wetmore's (1951) vitamins, 0.06 M sucrose, the growth regulators NAA at $0.1 \mu\text{M}$ and 2, isopentenyladenine (2,ip) at $2.5 \mu\text{M}$. Styles were most embryogenic at 35°C in the dark, with each explant giving 10–50 somatic embryos. Temperature was crucial in

somatic embryogenesis. Subsequently, Guedira *et al.* (1989) obtained somatic embryos from anthers of micropropagated plants, with anthers at the tetrad and microspore stages being the most responsive. As in the work of Dubois *et al.* (1988), darkness and a temperature of 35 °C were essential to induce somatic embryos on medium containing 0.02 mg l⁻¹ NAA and 0.5 mg l⁻¹ 2,ip. Glutamine and ammonium nitrate were most suitable as nitrogen sources. Some plants derived from somatic embryos showed phenotypic variation, such as anthocyanin-pigmented veins and narrow or indented leaves.

In addition to regenerating shoots by organogenesis as already discussed, the chicory cv. 474 produced somatic embryos. Robatche-Claive *et al.* (1992) investigated the process in leaf explants of 3-month-old plants, the material being incubated in the dark (35 °C) in agitated liquid medium. Histological studies confirmed the synchronous development of somatic embryos in explants cultured with 30 mM sucrose, the embryos increasing in number as the sucrose concentration increased to 360 mM.

In studies to further knowledge of the role of carbohydrates in somatic embryogenesis, Couillerot *et al.* (1993) used root segments, also from the cv. 474, to investigate the effects of cellobiose, fructose, galactose, glucose, lactose, maltose, melibiose, raffinose, sucrose, and trehalose (each at 120 mM) in the culture medium. Sucrose was most effective in maximizing the number of somatic embryos, although fructose, glucose, maltose, and raffinose resulted in satisfactory development of embryos. The embryogenic potential of explants was correlated with polyamines, which the authors detected in the induction medium after 5 days of culture. High concentrations were detected of putrescine, spermine, and spermidine in the medium that induced somatic embryos. In contrast, such compounds were not released from explants on a noninductive medium. However, it was not possible to synchronize the formation of somatic embryos from root explants of chicory, unlike the situation with leaf explants (Robatche-Claive *et al.*, 1992).

Following the report that temperature was a crucial parameter in somatic embryogenesis of spinach (Dubois *et al.*, 1988), Decout *et al.* (1994) investigated the effect of temperature on cultures of the chicory cv. 474. Wounding of

the leaf explants was essential to promote a response. After 5 days, cells near the wound sites commenced mitotic division, although the pattern of division was dependent on the incubation temperature. As in the work of Dubois *et al.* (1988), somatic embryogenesis was most pronounced at 35 °C, although organogenesis was poor at this temperature. Somatic embryos were infrequent at 25 °C; both somatic embryos and shoots developed at 30 °C. The authors suggested that temperature influences the cell cytoskeleton and microtubules, which subsequently affects the initiation of somatic embryogenesis.

Cell suspension cultures initiated from callus originating from the veins of fully developed leaves of the chicory cv. Witloof, also exhibited somatic embryogenesis (Mohamed-Yasseen and Splittstoesser, 1995). Callus was stimulated by placing leaf vein segments on semi-solidified MS-based medium containing 30 g l⁻¹ sucrose, 100 mg l⁻¹ casein hydrolysate, and 1.3 µM 2,4-D, and 1.3 µM kinetin. Cultures were incubated in the dark for 8–12 weeks and transferred to new medium every 4 weeks. Callus was maintained in liquid medium for 4–6 weeks. Transfer to liquid MS-based medium with 30 g l⁻¹ sucrose and 1.8 µM BAP, induced somatic embryos on all calli. Although the somatic embryos were hyperhydric (vitrified), they germinated on half-strength MS-based medium semi-solidified with 8 g l⁻¹ agar. Interestingly, glucanases were detected in the medium after incubating explants of the cv. 474 in the dark at 35 °C (Helleboid *et al.*, 1998), enzyme concentrations being three times more in the medium following the culture of embryogenic lines compared with nonembryogenic tissues. Subsequently, Helleboid *et al.* (2000) investigated the proteins released into the medium by culturing for 4 days leaf explants of embryogenic and nonembryogenic tissues of the cv. 474. Concentrations of proteins of 25, 32, and 38 kDa were eightfold greater in the embryogenic line, suggesting that they may be involved in somatic embryogenesis. As the concentration of carbohydrate in the culture medium is crucial in maintaining growth, Bellettre *et al.* (1999) investigated the influence on somatic embryogenesis of doubling the sucrose concentration from 30 mM to 60 mM with 330 mM glycerol, following the initial procedure of Dubois *et al.* (1988). Increasing the sucrose concentration not only reduced the

embryo induction period, but also stimulated the number of somatic embryos.

2.3 Spinach

2.3.1 Organogenesis in spinach

Spinach is less amenable to culture than lettuce or chicory, although cultured tissues are totipotent. Usually, seeds are germinated in the dark on half-strength MS-based medium lacking growth regulators at 20–25 °C. Removal of the pericarp may be essential to minimize contaminating micro-organisms (Sasaki, 1989; Molvig and Rose, 1994). Robust sterilization (e.g., immersion in 2–3% sodium hypochlorite solution for 2 h) may also be essential (Komai *et al.*, 1996a). Five to ten days old seedlings are normally used as a source of explants, although Al-Khayri *et al.* (1991) used leaves from 3-month-old plants as source material. Knoll *et al.* (1997) employed root explants from shoots that had been in culture for up to 24 months.

Several culture conditions have been reported to induce differentiation in spinach, including temperatures of 20 °C (Al-Khayri *et al.*, 1991) to 25 °C (Komai *et al.*, 1996b), and a 16 h photoperiod with a light intensity of 35–90 $\mu\text{mol m}^{-2} \text{sec}^{-1}$. Callus has also been initiated in continuous light (Mii *et al.*, 1992) and in the dark (Al-Khayri *et al.*, 1991; Molvig and Rose, 1994). MS medium has been employed most extensively, although Knoll *et al.* (1997) used Nitsch and Nitsch (1969) medium. Zdravkovic-Korac and Neskovic (1999) used a basal medium containing extra vitamins. Sucrose (10–30 g l^{-1}) has been the main carbon source, with the pH of culture media ranging from 5.8 to 6.5.

Adventitious shoot formation was reported from callus of seedling apices on MS medium with 4.65 μM kinetin and 2.89 μM GA₃ (Neskovic and Radojevic, 1973). Later, Sasaki (1989) cultured hypocotyl explants of the cvs. Wakakusa, Nippon, Toko, Hoyo, and Tokai on MS medium containing 20 g l^{-1} sucrose with various concentrations and combinations of GA₃ (0, 10⁻⁷, 10⁻⁶, 10⁻⁵, and 10⁻⁴ M) and 15 mg l^{-1} IAA. Adventitious shoot buds were observed in all cultivars except Tokai; callus of Nippon developed the most shoots. Interestingly, there was an inverse correlation between callus initiation and regeneration, since cultivars such as Nippon, exhibited poor callus

development, but maximum shoot regeneration. Shoots excised after 5–6 weeks, rooted on MS-based medium containing 10 mg l^{-1} IBA, flowered and set seed.

Al-Khayri *et al.* (1991) optimized organogenesis from leaf explants of 3-month-old plants of the cvs. High Pack, Grandstand, Baker, and Kent on MS medium with 2 mg l^{-1} kinetin and 0.1, 0.5, or 1.0 mg l^{-1} 2,4-D, in the dark, or with a 10 h photoperiod. Shoots were induced with the same concentration of kinetin and 0.1 mg l^{-1} 2,4-D, 1.0 mg l^{-1} GA₃, and 100 mg l^{-1} ascorbic acid. As in earlier studies, shoots were rooted with 1 mg l^{-1} IBA, the latter being more effective than other auxins (NAA, IAA, IBA, and 2,4-D). Al-Khayri *et al.* (1991) also found that cultivars that readily produced callus exhibited poor shoot regeneration, as reported by Sasaki (1989). Callus induced in the dark regenerated more shoots than callus in the light. Al-Khayri *et al.* (1991) stressed that the system was highly cultivar dependent and was not a general protocol. Shoots remained vegetative under short days but flowered under long-day conditions. In their subsequent experiments, Al-Khayri *et al.* (1992a) targeted the cvs. High Pack and Baker, which had exhibited previously the most shoot regeneration. Supplementation of the medium with 15% (v/v) coconut milk increased callus production from explants, reduced the time for callus initiation by 7 days, stimulated shoot formation and, overall, reduced the culture period by 8–7 weeks. The cv. High Pack was more responsive than Baker in producing shoots. Al-Khayri *et al.* (1992b) also investigated the role of GA₃ in the culture medium, since GA₃ was essential for shoot regeneration. GA₃ at 7.2 μM resulted in organogenesis from 70% of the explant-derived calli. Reduction of GA₃ to 1.4 μM was recommended for shoot multiplication, since concentrations above this value unexpectedly reduced plant height.

Kondo *et al.* (1991) also induced the multiplication of shoot primordia of the cvs. Minsterland and Jiromaru in liquid MS medium with 0.02–1 mg l^{-1} IAA and 2 mg l^{-1} BAP. Roots formed on shoots exposed to IBA at 0.2 mg l^{-1} , or when maintained on medium lacking growth regulators. In agreement with Komai *et al.* (1996c) and Zdravkovic-Korac and Neskovic (1999), plant regeneration was observed only in cultures with red pigmentation.

Other workers employed hypocotyl explants from 7 days old seedlings of the cv. Sunlight to induce callus on MS medium with 7 mg l^{-1} NAA, at pH 5.8–6.5 (Sato *et al.*, 1992). Mii *et al.* (1992) cultured 7-day-old explants from 9 spinach cultivars on Nitsch (1969) medium containing 10 mg l^{-1} IAA. This work again reflected cultivar differences, a phenomenon common to the culture of spinach tissues. Preculture of explants on medium with 5,6-Cl₂-IAA for 20 days before transfer to medium lacking growth regulators, was beneficial in stimulating shoot regeneration from hypocotyl-derived calli.

The regeneration procedure reported originally by Neskovic and Radojevic (1973) was used as a basis, with modification, to regenerate plants from cotyledons, roots, and hypocotyls of the cv. Hybrid 102 (Molvig and Rose, 1994). Growth of callus initiated in the dark on MS medium with $4.6 \mu\text{M}$ kinetin and $4.5 \mu\text{M}$ 2,4-D, was enhanced by a 16 h photoperiod on medium with the same concentration of kinetin, but with $2.9 \mu\text{M}$ GA₃ replacing 2,4-D. Shoots and roots were observed on the explants after several culture cycles, each of 4–6 weeks duration. Shoots excised and transferred to hormone-free medium developed into plants.

Following the report of Molvig and Rose (1994), Xiao and Branchard (1995) cultured hypocotyl and root explants on MS medium containing $85.6 \mu\text{M}$ IAA and $100 \mu\text{M}$ GA₃. These elevated concentrations of growth regulators induced more than 90% of the root explants to produce adventitious shoots. In contrast, hypocotyl explants were less responsive, with only 75% of the explants regenerating shoots. Ninety-two percent of the shoots excised and cultured on medium with 2.9 – $5.7 \mu\text{M}$ IAA developed roots. Zhang and Zeevaart (1999) described a rapid and efficient procedure for regenerating plants from cotyledons of 5-day-old seedlings of the cv. Longstanding Bloomsdale Dark Green that was exploited later to generate transgenic plants of spinach.

2.3.2 Somatic embryogenesis in spinach

One of the first reports of somatic embryogenesis in spinach was that of Xiao and Branchard (1993) who cultured hypocotyl explants of the cv. Carpo on semi-solid MS-based medium supplemented

with 3% sucrose, 0.01 mg l^{-1} biotin, 250 mg l^{-1} glutamine, 15 mg l^{-1} IAA, and 34.6 mg l^{-1} GA₃. Callus was induced in the dark followed by a 10-h photoperiod preceding continuous light. Somatic embryos were induced after transfer of callus to liquid medium with 0.5 mg l^{-1} IAA and 3.5 mg l^{-1} GA₃ in continuous light; reduction in IAA concentration was essential for somatic embryogenesis. Somatic embryos developed into plants in liquid medium containing 0.5 mg l^{-1} IBA under continuous light. Subsequent studies focused on the cv. Jiromaru (Komai *et al.*, 1995), somatic embryos being initiated from root explants of 10-day-old seedlings on MS medium with 20 g l^{-1} sucrose combined with 10 or $30 \mu\text{M}$ NAA and 0– $100 \mu\text{M}$ GA₃. A nitrate:ammonium ratio of 2:1 in the medium stimulated callus induction. After 28 days exposure to a 16-h photoperiod, cells were cultured in liquid or on semi-solid MS medium lacking growth regulators to induce embryogenesis. Most plants were regenerated from cell masses in liquid medium, with somatic embryos being detected at all stages of development. As in organogenesis, GA₃ in the callus induction medium was essential for somatic embryogenesis.

In extending their work, Komai *et al.* (1996c) concentrated on the details of somatic embryogenesis. Explants of cotyledons, roots, hypocotyls, and leaves from eight cultivars were cultured on six different media with 10 g l^{-1} sucrose, $0.1 \mu\text{M}$ GA₃, and $10 \mu\text{M}$ NAA. Root explants of the cvs. Jiromaru, Hoyo and Nihon produced the most embryogenic tissues compared with the cvs. King of Denmark, Ujo, Minsterland, Viroflay, and Nobel; half-strength MS-based medium was the most suitable for callus induction and somatic embryo formation. Komai *et al.* (1996d) also targeted root explants of the cv. Jiromaru, their growth regulator studies including IAA, IBA, NAA, 2,4-D, 2-ip, kinetin, BAP, N-(2-chloro-4-pyridyl)-N'-phenylurea (CPPU), and GA₃, either individually or in combination. Callus was induced on medium with all of the auxins assessed, 30 or $100 \mu\text{M}$ IBA with 10 or $30 \mu\text{M}$ NAA inducing the optimum response. GA₃ was essential for the formation of embryogenic callus.

Komai *et al.* (1996b) also studied the effect of carbohydrate on somatic embryogenesis using the cv. Jiromaru and the culture conditions that they established earlier. They modified

the medium with 29, 87, or 145 mM glucose, galactose, mannose, fructose, sorbose, maltose, cellobiose, lactose, or raffinose replacing sucrose. Embryos developed on medium with most of the carbohydrates assessed, although somatic embryogenesis was optimal with 29 mM fructose, this possibly being related to fructose being metabolized in preference to other carbohydrates. In contrast to the results of Komai *et al.* (1996c), Zdravkovic-Korac and Neskovic (1999) found that GA₃ and IAA suppressed somatic embryogenesis, whereas ABA (4 μ M) stimulated this process. Disks from fully expanded young leaves of the cv. Matador were cultured on MS-based medium containing 20 g l⁻¹ sucrose, 100 mg l⁻¹ myo-inositol, 2.0 mg l⁻¹ thiamine hydrochloride, 2.0 mg l⁻¹ pyridoxine hydrochloride, 2.0 mg l⁻¹ adenine, 5.0 mg l⁻¹ nicotinic acid, 4.4 μ M 2,4-D, and 4.6 μ M kinetin. Embryo induction occurred on transfer of explants to medium lacking 2,4-D, but supplemented with ABA, GA₃, or IAA. In agreement with the earlier studies of Komai *et al.* (1996c), embryos formed only from red pigmented callus. Somatic embryos were easily distinguished from the parental callus and any developing buds, since tissues regenerated simultaneously by organogenesis. Ethylene in somatic embryogenesis was investigated using root explants of the cv. Nippon (Ishizaki *et al.*, 2000). Inclusion of 10 μ M ethephon in callus induction medium increased by 50% the initiation of embryogenic callus. The authors suggested that although ethylene may be critical during the early stages of callus initiation, it later inhibits somatic embryo development.

3. PROTOPLAST-TO-PLANT SYSTEMS FOR GENE TRANSFER IN LEAFY VEGETABLES

3.1 Protoplasts and Somatic Hybridization in Lettuce

Protoplast fusion circumvents pre- and postzygotic barriers often associated with sexual hybridization, enabling the introgression of useful genetic traits into cultivated species, as in *L. sativa* from sexually incompatible *Lactuca* species. In lettuce, protoplast-to-plant systems have been developed as a basis for gene transfer by somatic hybridization for *L. sativa* with wild *Lactuca*

species, including *L. serriola*, *L. saligna*, and *L. virosa* (Webb *et al.*, 1994). General procedures of protoplast isolation, chemical and/or electrical fusion, and the culture conditions to generate somatic hybrid plants, are summarized in reviews by Davey *et al.* (2000a, b, 2005a, b, c). Examples of somatic hybrid plants in lettuce include those between *L. sativa* and *L. perennis* or *L. tartarica* (Chupeau *et al.*, 1994; Maisonneuve *et al.*, 1995), *L. sativa* with *L. virosa* (Matsumoto, 1991), *L. sativa* with *L. debilis* or *L. indica* (Mizutani *et al.*, 1989), and *L. sativa* with *L. serriola* (Matsumoto, 1987). Somatic hybrids of *L. sativa* (+) *L. tartarica* were sensitive to climatic conditions (Maisonneuve *et al.*, 1995), and did not set seed after pollination by donor cultivars. Resistance to downy mildew was transferred from *L. tartarica* into *L. sativa*, but fertility of the resulting hybrids was low. Somatic hybrids of *L. sativa* (+) *L. virosa* were generated in order to transfer resistance to *Nasonovia ribisnigri* (leaf aphid), *Erysiphe cichoracearum* (powdery mildew), and *Pseudomonas cichorii* (bacterial rot) from the wild species into the cultivated crop. Subsequently, Mizutani and Tanaka (2003) analyzed isozymes in lettuce and the wild species *L. serriola*, *L. saligna*, *L. virosa*, and *L. indica*. Enzyme polymorphism revealed that the somatic hybrid between lettuce and *L. indica* was composed of 4 genomes of *L. sativa* and 2 genomes of *L. indica*, such polymorphisms being useful genetic markers in lettuce breeding. There are no reports of the detailed evaluation of somatic hybrids, especially under field conditions.

3.2 Protoplasts and Somatic Hybridization in Chicory

In chicory, protoplast-derived cell colonies often became necrotic with plant regeneration being difficult to stimulate, despite protoplast plating efficiencies of 60–80% (Crepigny *et al.*, 1982). Young leaves from glasshouse-grown plants of the cv. Red Witloof released protoplasts when incubated with a wall degrading enzyme mixture consisting of 0.02% (w/v) Macerozyme, 0.1% (w/v) Onozuka Cellulase R10, and 0.05% (w/v) Driselase. Cells were cultured on MS-based medium supplemented with Heller's (1953) microelements, Morel and

Wetmore's (1951) vitamins and 5 g l^{-1} sucrose, the survival of protoplast-derived colonies was stimulated with glutamine (10 mM) as the sole nitrogen source. Protoplast-derived callus developed buds, but only limited numbers of plants were regenerated on medium with 0.5 mg l^{-1} IAA and 1 mg l^{-1} BAP. Following these investigations, Saksi *et al.* (1986) prepared protoplasts from leaves of 21-day-old axenically grown seedlings of the Witloof cv. Flash, the medium of Crepy *et al.* (1982) being supplemented with 1.0 mg l^{-1} of both BAP and NAA. Again, glutamine was essential to division of protoplast-derived cells, while sucrose at 5.0 g l^{-1} was advantageous for protoplast growth. Shoots formed on protoplast-derived callus cultured on medium in which NH_4NO_3 was replaced by glutamine, and supplemented with 0.05 mg l^{-1} NAA and 0.5 mg l^{-1} BAP. Plants were transferred to the glasshouse after 4–5 months. Generally, young leaves have been the preferred source material, in terms of protoplast yield, as tissues from roots, stems, bracts, and callus, gave poor yields (Chupeau, 1989). Optimization of plant growth conditions was crucial in maximizing the yields of viable protoplasts (Chupeau, 1989; Rambaud *et al.*, 1990).

The chicory cv. 474, known to be highly embryogenic from earlier studies, was exploited to develop protoplast-to-plant systems. Mesophyll protoplasts cultured on half-strength MS-based medium lacking NH_4NO_3 but containing Heller's (1953) microelements, Morel and Wetmore's (1951) vitamins, 375 mg l^{-1} glutamine, 150 mg l^{-1} myo-inositol, 5 g l^{-1} sucrose, and 90 g l^{-1} mannitol, together with $10.7 \text{ } \mu\text{M}$ NAA and $5.0 \text{ } \mu\text{M}$ 2,ip, developed into somatic embryos by 3 procedures (Sidikou-Seyni *et al.*, 1992). First, 7-day-old protoplast-derived callus were transferred to semi-solid medium with 500 mg l^{-1} glutamine, 50 g l^{-1} mannitol, and 20 g l^{-1} sucrose and supplemented with $0.5 \text{ } \mu\text{M}$ NAA and $2.5 \text{ } \mu\text{M}$ 2,ip. In the second procedure, protoplast-derived colonies were transferred to medium optimized for somatic embryo induction, with $0.1 \text{ } \mu\text{M}$ NAA and $2.5 \text{ } \mu\text{M}$ 2,ip (Dubois *et al.*, 1988). Thirdly, well-developed callus was transferred to the same somatic embryo induction medium. Embryos developed when transferred to agitated liquid Heller's (1953) medium containing $0.15 \text{ } \mu\text{M}$ GA_3 , followed by germination on semi-solid Heller medium lacking

growth regulators. A callus stage was essential in the development of single protoplasts to embryos. Regenerated plants were morphologically normal and fertile.

Plants have also been regenerated from protoplasts of Italian red chicory cultivars (Varotto *et al.*, 1997), the cv. 363 giving 10 plants per protoplast-derived callus. Subsequently, Nenz *et al.* (2000) compared the culture of leaf mesophyll protoplasts of the cv. Rosso di Chioggia in liquid medium, semi-solid medium, and after embedding in droplets of alginate-solidified medium. Protoplasts in droplets of calcium alginate produced plants within 2 months. The plating efficiency was maximal (56.2%) on medium with 8 g l^{-1} mannitol, 10 mg l^{-1} NAA, and 4.5 mg l^{-1} BAP. The same medium also resulted in optimum division frequency (35.9%) of protoplast-derived cells.

In contrast to lettuce, there is only one report of the transfer of genetic material into chicory by intergeneric protoplast fusion. Varotto *et al.* (2001) generated male sterile asymmetric hybrids (cybrids) by fusing iodoacetic acid inactivated mesophyll protoplasts from a red chicory genotype CH363 with γ -irradiated hypocotyl protoplasts of a male sterile line of sunflower (CMSHA89). Mixing protoplasts in a 3:1 or 1:1 ratio (chicory to sunflower), followed by fusion with polyethylene glycol (PEG), and culture in alginate droplets (Nenz *et al.*, 2000) resulted in plant regeneration, three plants of which were asymmetric hybrids. Such cybrids were morphologically similar to the chicory parent. However, their anthers contained less pollen at anthesis than plants of the genotype CH363 and failed to undergo self-pollination.

3.3 Protoplasts of Spinach

Otsuki and Takebe (1969) pioneered the isolation of spinach protoplasts to investigate chloroplast physiology. Later, Rose (1980) cultured protoplasts from leaves of 3-week-old seedlings on MS medium with 0.5% sucrose, 0.4 M sorbitol, and 0.4 M mannitol. Protoplasts prepared in the presence of Ca^{2+} and incubated under reduced light showed 50% survival after 8 days of culture. Cell wall regeneration was inhibited in the dark. Goto and Miyazaki (1992) were the first investigators to

regenerate plants from leaf protoplasts of the cv. Jiromaru, mitotic division of protoplast-derived cells leading to cell colony formation on half-strength MS medium containing 5 mg l^{-1} BAP and 1 mg l^{-1} 2,4-D. As reported by Rose (1980), protoplasts were cultured at $1 \times 10^5 \text{ ml}^{-1}$ at 25°C under reduced light for 7 days, before transfer to stronger light conditions. Adventitious shoot formation was induced on MS medium with 1.0 mg l^{-1} kinetin and 1.0 mg l^{-1} zeatin, or various combinations of BAP and NAA; shoots were rooted in liquid MS medium with 1 mg l^{-1} IBA or 1 mg l^{-1} IAA. Subsequently, Goto *et al.* (1996) stimulated organogenesis using the same approach, but with the addition of KM8P vitamins (Kao and Michayluk, 1975) and 0.5 M glucose as osmoticum in the culture medium to increase the protoplast plating efficiency. Adjustment of the pH of the shoot regeneration medium to 6.3 promoted rooting of regenerated shoots. In analyzing the regeneration of protoplast-derived tissues of seven spinach cultivars, Goto *et al.* (1998a) reported that the plating efficiencies and cell colony formation of the cvs. Ujo, Jiromaru, Hojo, and Minsterland exceeded those of Sapporo-aba, Viroflay, and Viking. Shoot regeneration from callus was not observed in the latter three cultivars, again emphasizing cultivar-specific responses. Smooth seeded spinach cultivars were less amenable to culture than prickly seeded varieties.

Concurrent with the studies of Goto *et al.* (1996), Komai *et al.* (1996a) described somatic embryogenesis from protoplasts of cotyledons, roots and hypocotyls from 10-day-old seedlings, and from leaves of 30-day-old plants of the cv. Jiromaru. These studies were based on their results of somatic embryogenesis from cultured root explants (Komai *et al.*, 1996b). Isolated protoplasts were cultured on a medium similar to that described by Goto and Miyazaki (1992), but with $1 \mu\text{M}$ 2,4-D or $10 \mu\text{M}$ NAA and $10 \mu\text{M}$ zeatin. An extended dark period of 21 days at 25°C was followed by transfer to reduced light for a further 21 days, during which time the cultures were diluted every 3 days with new medium. Protoplast-derived cells produced callus when the medium was supplemented with 30 mM sucrose, 30 mM glucose, 500 mg l^{-1} casein hydroxylate, $0.3 \mu\text{M}$ 2,4-D, and $3 \mu\text{M}$ zeatin, whilst maintaining the cultures under a 16 h photoperiod; somatic embryos formed on protoplast-derived

callus when the growth regulators were changed to $0.1 \mu\text{M}$ GA₃ with $10 \mu\text{M}$ NAA. Adventitious roots were also induced from protoplast-derived callus. Importantly, these roots could be stimulated to produce multiple somatic embryos on MS-based medium supplemented with 30 mM fructose.

In optimizing the efficiency of the protoplast-to-plant system, Goto *et al.* (1999a) evaluated the effect of organic acids on cell division and shoot multiplication. Citric acid at 0.1 M, and other organic acids, were beneficial in the presence of 0.5 M glucose, enhancing the division of protoplast-derived cells, callus formation, and shoot regeneration. In the presence of 0.1 M citric acid, cell division was recorded in protoplast cultures at plating densities of $20 \times 10^4 \text{ ml}^{-1}$. Leaves from 25-day-old seedlings were the preferred source material for the isolation of viable, totipotent protoplasts. There are no studies of the culture of spinach protoplasts after 1999 and no reports of the exploitation of isolated protoplasts in somatic hybridization in this leafy vegetable.

4. TRANSFORMATION OF LEAFY VEGETABLES

The labor-intensive procedures associated with gene transfer by protoplast fusion have encouraged workers to focus attention on genetic modification by transformation. Additionally, recent advancements in recombinant-DNA technology have facilitated the delivery of specific genes to target species without the transfer of other, often unwanted, genetic traits that occurs during sexual and somatic hybridization.

4.1 Transformation of Lettuce

4.1.1 Basic procedures

Initial investigations in lettuce established reliable transformation protocols for this crop, exploiting protoplast-to-plant systems then available. Leaf protoplasts were electroporated in the presence of either pCAMV CAT, carrying the chloramphenicol acetyltransferase (*cat*) gene driven by the cauliflower mosaic virus (CaMV) 35S RNA promoter, or pABD1 with the neomycin

phosphotransferase (*nptII*) gene (Chupeau, 1989). The *cat* gene was used to demonstrate transient gene expression. The selection of kanamycin resistant plants following transformation with pABD1 and subsequent analysis of their seed progeny, confirmed that antibiotic resistance was inherited as a dominant Mendelian trait with integration of foreign DNA into the genomic DNA of antibiotic resistant plants. Despite this initial progress, few lettuce genotypes were transformed by direct DNA uptake into isolated protoplasts because of the requirement to first establish a plant regeneration system. Consequently, protoplast transformation was superseded by *Agrobacterium*-based transformation systems. The molecular biology of *Agrobacterium*-mediated gene delivery has been summarized in several excellent reviews (Gelvin, 2003; Valentine, 2003; Lacroix *et al.*, 2006; Tzfira and Citovsky, 2006), together with recent developments in the construction of gene vectors (Cheng *et al.*, 2004; Chung *et al.*, 2005).

In early transformation experiments, Micheltore *et al.* (1987) used wild type octopine (ACH5) and nopaline (C58) strains of *Agrobacterium tumefaciens* to induce crown galls on explants of cotyledons from 4-day-old seedlings of the Butterhead cv. Cobham Green. The unusual amino acids octopine or nopaline, characteristic of tumors incited by *A. tumefaciens* strains ACH5 and C58, respectively, were synthesized by the resulting tumors. The same investigators also used the engineered strain, GV3111 of *A. tumefaciens* harboring the cointegrate vectors pTiB6S3, pMON120, or pMON200, or the binary vector pMON505. Plasmid MON200 carried the chimaeric *nptII* gene with a *nos* (nopaline synthase) promoter and terminator (*nos.nptII.nos*). Explants transformed by GV3111 carrying either pMON200 or pMON505, produced callus on medium with 50 mg l⁻¹ of kanamycin sulfate; shoots were regenerated following transformation experiments with the disarmed pTiB6S3. These initial studies provided evidence that the lettuce genome could be manipulated using *A. tumefaciens*-mediated gene delivery. Subsequently, the cv. Kayser was transformed by *A. tumefaciens* strain LBA4404 harboring the binary vector pTRA415 (Enomoto *et al.*, 1990). The vector carried the *nptII* gene as the selectable marker, and the β -glucuronidase (*gus*) reporter gene. The latter was driven by the CaMV 35S promoter, or

the stress or salicylic acid-inducible pathogenesis-related (PR) 1a protein-encoding gene promoter from tobacco. GUS activity increased 3- to 50-fold in PR-*gus* transformed plants, confirming that the transgene was expressed normally under the regulated control of the *PR 1a* promoter. Vectors constructed by the Monsanto company were used in early studies of lettuce transformation, as in Lake Nyah with *A. tumefaciens* carrying the cointegrate vector pMON200 (Webb, 1992). Transgenic plants of the cv. South Bay were also generated using *A. tumefaciens* strain A208 with the engineered Ti plasmid, pTiT37SE, or the binary vectors pMON9749 or pMON9793 (Torres *et al.*, 1993). Expression of the *gus* gene in transgenic plants was confirmed histochemically, while PCR and Southern hybridization analyses showed integration of the transgene into the genome of transgenic plants.

The protocols employed in these early investigations were often genotype dependent. Therefore, Curtis *et al.* (1994a, 1995) focused attention on developing a reliable, genotype-independent protocol for *A. tumefaciens*-mediated transformation of 13 lettuce cultivars, including Crisphead cultivars that previously had been difficult to transform. Cotyledons of 7-day-old seedlings were inoculated with *A. tumefaciens* strains 0065 or 1065 with the binary vector pMOG23 carrying the chimeric *nos.nptII.nos* gene and a CaMV 35S *gus*-intron reporter gene. Strain 1065 was supervirulent as it also carried pTOK47 with extra copies of the Ti plasmid virulence genes *virB*, *virC*, and *virG*. Supervirulence was essential for transforming some cultivars, such as Reflex (Curtis *et al.*, 1994a). The bacterial density of the inoculum was crucial with respect to transformation, as suggested earlier by Micheltore *et al.* (1987). Minor modifications of the transformation protocol were described by Davey *et al.* (2001). The ease of transforming lettuce with *Agrobacterium* was stated by Wroblewski *et al.* (2005), who used *L. sativa* cvs. Valmaine and Mariska and the wild lettuce *L. serriola* (LS102) in transient *gus* expression assays. The laboratory strain C58C1 of *A. tumefaciens* was reliable for delivering genes to lettuce.

Whilst gene insertion by *Agrobacterium* is the procedure of choice, transgene expression may be inconsistent in lettuce (Davey *et al.*, 2001). The choice of promoters is crucial for stable

gene expression. Gene copy number and DNA methylation also influence transgene expression in this leafy vegetable. In their evaluation of gene expression in the cv. Evola, McCabe *et al.* (1999b) showed that expression of the *bar* gene for resistance to the herbicide glufosinate ammonium, was more consistent in T₁, T₂, and T₃ seed generations when the gene was driven by the -784 plastocyanin (*petE*) promoter from pea, compared to the CaMV promoter. This difference in gene expression was probably related to the fact that the CaMV promoter has 59 possible methylation sites per kb of DNA compared to 18 per kb for the *petE* promoter. Other workers also used the CaMV 35S promoter in lettuce (Enomoto *et al.*, 1990; Curtis *et al.*, 1994a, b; Pang *et al.*, 1996; McCabe *et al.*, 1999a), and the *nos* (Michelmore *et al.*, 1987; Yang *et al.*, 1993; Curtis *et al.*, 1994a, 1996a, b; McCabe *et al.*, 1999a), *Mac* (Curtis *et al.*, 1994b), *petE* (McCabe *et al.*, 1999b), and *ACT1* (McCabe *et al.*, unpublished) promoters. The tobacco pathogenesis-related protein gene promoter *PR1a* resulted in *gus* gene expression following its induction by salicylic acid (Enomoto *et al.*, 1990), while the *Mas* (mannopine synthase) promoter gave in root-specific expression (Curtis *et al.*, 1994b); the tapetum-specific promoter, *A9*, was used to induce male sterility in lettuce (Curtis *et al.*, 1996b). Transformation of the cv. Evola with the *ipt* (isopentenyl phosphotransferase) gene from *A. tumefaciens* driven by the senescence-specific promoter, *SAG12*, from *Arabidopsis thaliana*, resulted in a 48-fold increase in zeatin riboside equivalents in leaves of 60-day-old plants.

As in many transgenic plants, transfer DNA (T-DNA) integration into lettuce may be complex (McCabe *et al.*, 1999a), with little or no correlation between gene copy number and transgene expression. Post-transcriptional gene silencing was correlated with transgene dosage in lettuce transformed with a tomato spotted wilt virus N (TSWV N) coat protein gene with the CaMV 35S promoter (Pang *et al.*, 1996). The demethylating agent 5-azacytidine was used to alleviate silencing of the CaMV 35S-*gus* gene in transgenic plants of the cv. Raisia (McCabe *et al.*, 1999a). Clearly, several factors may contribute to transgene silencing, including the complexity of the lettuce genome with its heterochromatic or repetitive DNA (Stam *et al.*, 1997) and methylation. Transgene insertion into highly

methylated regions of the genome also results in transgene inactivation (Pröls and Meyer, 1992). Exploiting supervirulent strains of *Agrobacterium* for lettuce transformation may result in multiple T-DNA insertions at different genomic loci, increasing the probability of transgene integration at sites that are not susceptible to methylation and gene silencing (McCabe *et al.*, 1999a).

4.1.2 Introduction of agronomically important genes into lettuce

Several genes of agronomic importance have been introduced into lettuce, with considerable advances being made during the last decade.

4.1.2.1 Herbicide tolerance

Resistance to herbicides and disease is a prime target for genetic manipulation since these agents cause severe crop losses. Herbicide resistance has been introduced into lettuce from both academic and commercial perspectives. Thus, Mohapatra *et al.* (1999) introduced the *bar* gene from the bacterium *Streptomyces hygroscopicus* into seedling cotyledons of the cv. Evola by *Agrobacterium*-mediated transformation with strains 0310 and 1310. The strain 1310 carried the hypervirulent pTOK47 in addition to the binary vector with the *nptII* and *bar* genes. Plasmid TOK47 in strain 1310 gave multiple insertions of T-DNA into some plants, whereas strain 0310 gave single gene inserts in all plants analyzed by DNA-DNA hybridization. Axenic seedlings grew on medium with glufosinate ammonium at 5 mg l⁻¹, while glasshouse-grown plants were resistant to the herbicide when the latter was sprayed on the plants at 300 mg l⁻¹. This investigation confirmed that herbicide resistance can be introduced into lettuce with stable expression in seed generations. Although sexual hybridization has been used to transfer sulfonylurea resistance into cultivated lettuce from the wild species, *L. serriola* (Mallory-Smith *et al.*, 1990), sexual incompatibility and lack of availability of herbicide resistance in the *Lactuca* gene pool limit further introgression of herbicide tolerance into the cultivated crop to transformation-based procedures.

4.1.2.2 Virus resistance

Experiments have been conducted to introduce virus resistance into lettuce using a coat protein gene-mediated approach, Pang *et al.* (1996) transferring the nucleocapsid (N) protein gene of the lettuce tospovirus, TSWV, into two lettuce breeding lines. Transgenic plants expressing the nucleocapsid (N) protein gene were protected against TSWV. In studies with lettuce infectious yellows virus (LIYV), Falk (1996) was unable to detect LIYV resistance in transgenic lettuce, although the same construct resulted in virus resistance in tobacco. Dinant *et al.* (1993) also introduced a LMV coat protein (LMV-CP) gene into LMV-susceptible lettuce, but the transgene conferred only poor resistance to this virus. Loss of virus resistance was more pronounced in lettuce during subsequent seed generations, an observation also made by Gilbertson (1996). Dinant *et al.* (1997) also introduced the coat protein gene from LMV strain O into the virus-susceptible cvs. Girelle, Jessy, and Cocarde. Several transgenic plants accumulated LMV-CP. As in other examples of potyvirus sequence-mediated protection, some plants were completely virus resistant, but in others this resistance was not sustained, with the development of viral infection symptoms. The efficiency of this strategy to induce LMV resistance was considered to be related to the developmental stage of the transgenic plants at the time of their inoculation with the virus.

Simple but robust procedures are useful in assessing viral resistance of plants. Mazier *et al.* (2004) used explant-derived shoots and *in vitro* grown seedlings to assess lettuce cultivars for their resistance to LMV. Excellent correlation was obtained in cultivars already known to be LMV resistant and their resistance after virus inoculation of *in vitro* grown material. This procedure, with its limited space requirements and environmental safety, should be especially useful in handling recombinant viruses.

4.1.2.3 Fungal and insect resistance

In attempts to understand the molecular basis for resistance to the fungus *B. lactucae*, Okubara *et al.* (1997) generated transformed plants of the cv. Diana using *A. tumefaciens* carrying

constructs with the maize *Ac* transposase and *Ds*. Their studies showed that several *Dm* genes for resistance to downy mildew were located in four clusters in the lettuce genome, with the largest cluster containing at least nine genes. More information, relating to *Dm* genes, has been discussed by Jeuken and Lindhout (2002). *Sclerotinia sclerotiorum* induces rot in crops, especially lettuce, pathogenesis being associated with the production of oxalic acid. Thus, in studies to decrease synthesis of this compound, Dias *et al.* (2006) introduced the decarboxylase (*oxdc*) gene from *Flammulina* sp. into lettuce, and showed that leaves from two transgenic plants inoculated with agar plugs of a 2-day-old culture of *S. sclerotiorum* failed to develop disease symptoms. Since verticillium wilt incited by *Verticillium dahliae* is also a major threat to lettuce cultivation, particularly in California, Vallad *et al.* (2006) inoculated the susceptible cvs. Saunas and Sniper and the resistant cvs. La Brillante and Little Gem with 29 isolates of *V. dahliae* and two isolates of *Verticillium albo-atrum*. Molecular evidence from the intergenic spacer region of the nuclear ribosomal RNA gene suggested that certain isolates form a phylogenetically distinct subgroup that differs in virulence toward specific lettuce cultivars. Such information may have relevance in directing the targeting of genes for *Verticillium* resistance to certain lettuce cultivars. Ferritin, an iron storage protein, sequesters iron in plants. Following earlier studies with tobacco in which overproduction of ferritin reduced oxidative stress and improved tolerance to pathogens by sequestering free-iron that would normally produce iron-mediated Fenton oxidants, such as hydroxyl radicals (OH•) (Deak *et al.*, 1998), Goto *et al.* (2000) transformed lettuce with the CaMV 35S promoter driving the soybean ferritin complementary DNA (cDNA), with the *nptII* gene for kanamycin selection of transgenic plants. Transgenic plants accumulated 1.2- to 1.7-fold more iron than wild-type plants and grew faster than the latter, possibly related to a reduction of iron-mediated Fenton oxidants, such as hydroxyl radicals.

Sesquiterpene lactones play a role in disease resistance through the phytoalexin response. Such compounds include lactucin and lettucenin A. Thus, Bennett *et al.* (2002) cloned genes for germacrene A synthases in order to change the

profile of these latex-expressed compounds and to enhance disease and insect resistance using sense and antisense approaches in lettuce.

Transformation of plants with proteinase inhibitors that act on proteolytic enzymes may confer resistance to pests and pathogens. In studies of the role of the proteinase inhibitor II, *SaPIN2a*, from *Solanum americanum*, Xu *et al.* (2004) transformed lettuce with the *SaPIN2a* gene driven by the CaMV 35S promoter and suggested that this approach may be exploited to counteract pest and pathogen attack. Subsequently, Fan and Wu (2005) also introduced a *PIN2* gene into lettuce and Chinese flowering cabbage (*Brassica campestris* ssp. *parachinensis*), while Chye *et al.* (2006) extended these investigations to show that expression of *SaPIN2a* in lettuce conferred resistance to cabbage looper (*Trichoplusia ni*) caterpillars.

4.1.2.4 Drought, cold, and salinity tolerance

Drought and cold restrict the performance of lettuce, especially under field conditions. Curtis *et al.* (1996a) transformed the lettuce cv. Lake Nyah with the *rolAB* genes from *Agrobacterium rhizogenes* to stimulate root formation, with the aim of increasing drought tolerance. Expression of the *rolAB* genes may also increase the endogenous concentration of auxin, reducing the incidence of leaf russet spotting. Pileggi *et al.* (2001) focused attention on the development of crops under conditions of drought, salinity, and cold by transforming the cv. Grand Rapids with a mutated *P5CS* gene for δ -1-pyrroline-5-carboxylate synthase, that catalyzes two steps of proline biosynthesis in plants. The mutated gene is insensitive to feedback inhibition by proline. Increased concentration of proline acts like an osmoprotectant that could confer resistance to drought, salinity, and cold on transgenic plants. Transgenic lettuce plants obtained in these studies were tolerant to freezing.

Abdel-Kader (2001) studied drought-induced stress in the cvs. Longifolia-baladi and Crispamignonette. The results showed that drought induced lipid peroxidation and catalase activity, but decreased protein content, peroxidase and esterase activities. GA treatment of plants alleviated the drought effects. Vanjildorj *et al.* (2005) also targeted drought and cold tolerance

in lettuce by overexpressing the *Arabidopsis ABF3* gene, encoding a transcription factor for the expression of ABA responsive genes, in the lettuce cv. Chongchima. Transgenic plants were phenotypically normal, produced seed, and were more tolerant than wild-type plants to drought and cold stresses.

Salinity limits crop production in many areas, particularly on marginal lands and where crops have been irrigated intensively. Consequently, increased salt tolerance is a key target for transformation. In this respect, Park *et al.* (2005) introduced a late embryogenesis abundant protein gene from *Brassica napus* into lettuce. The six transgenic plants generated exhibited enhanced growth compared to nontransformed plants under salt stress imposed by exposure to 100 mM sodium chloride.

4.1.2.5 Taste, nutritional value, and anticancer activity

Kisiel *et al.* (1995) used *A. rhizogenes* strain LBA9402 to transform leaf explants from axenic seedlings of *L. virosa*, this *Lactuca* species being a traditional medicine because of its analgesic and sedative properties. The latter properties result from sesquiterpene lactones, which accumulate mainly in the latex. Transformed roots were induced and cultured to maximize biomass production and to facilitate analysis of secondary products. Eight sesquiterpene lactones were isolated from transformed roots.

Cultivated lettuce often has a bitter taste. In attempts to reduce bitterness, Sun *et al.* (2006) cloned the gene for the sweet and taste-modifying protein, miraculin, from the pulp of berries of *Richadella dulcifica*, a West African shrub. This gene, with the CaMV 35S promoter, was introduced into the cv. Kaiser using *A. tumefaciens* GV2260. Expression of the gene in transgenic plants resulted in the accumulation of significant concentrations of the sweet-enhancing protein. Since miraculin is active at extremely low concentrations, it may be used by diabetics as a food sweetener. Genes for other taste-modifying proteins, such as thaumatin, monellin, mabinlin, pentadin, brazzein, and curculin, have been cloned and sequenced and are available for insertion and expression in lettuce and other crop plants (Faus, 2000).

In addition to enhancing disease resistance, manipulation of sesquiterpene lactones in lettuce may also be exploited to reduce bitterness (Bennett *et al.*, 2002). Vitamin E, that includes tocopherols, are lipid soluble antioxidants, with tocopherol existing in the α , β , γ , and δ isoforms. The relative vitamin E potencies of these isoforms are 100%, 50%, 10%, and 3%, respectively. Cho *et al.* (2005) expressed a cDNA encoding γ -tocopherol methyltransferase from *A. thaliana* in the lettuce cv. Chungchima in efforts to improve tocopherol composition. Transgene inheritance and expression in transformed plants increased enzyme activity and conversion of γ -tocopherol to the more potent α form. As Cho *et al.* (2005) emphasized, conversion of γ -tocopherol to α -tocopherol in major food crops could increase their value and importance in human health, since vitamin E reduces the risk of several serious disorders. The latter include cardiovascular disease and cancer, in addition to slowing ageing and enhancing the function of the immune system.

Stilbenes, especially resveratrol, show cancer chemopreventative activity and have a role in the prevention of coronary heart disease and arteriosclerosis. Stilbene synthase is the key enzyme in resveratrol biosynthesis, with several stilbene synthase genes being isolated recently. Although lettuce contains the substrates for stilbene synthase, resveratrol is not synthesized. Thus, in order to engineer lettuce for synthesis of this compound, Liu *et al.* (2006) fused a cDNA encoding stilbene synthase from *Parthenocissus henryana* to the CaMV 35S promoter with the *bar* gene as a selectable marker. The expression construct was flanked by matrix attachment regions to maximize expression of the gene of interest in transgenic plants. Quantitative analysis showed that resveratrol in transgenic plants was $56.0 \pm 5.52 \mu\text{g g}^{-1}$ leaf fresh weight, comparable to that in the skin of grape fruit. In addition, an anticancer assay with HeLa cells showed that apoptosis was induced by 200 μM resveratrol extracted from lettuce leaves.

4.1.2.6 Accumulation of trace elements and nitrate

Zinc is an essential element in human nutrition, as its deficiency severely impairs organ function. In experiments to fortify lettuce with this

element, Zuo *et al.* (2002) expressed a mouse metallothionein mutant β -cDNA in the cv. Salinas 88 following *Agrobacterium*-mediated gene delivery. The concentration of zinc in transgenic plants increased to $400 \mu\text{g g}^{-1}$ dry weight, this being considerably more than in wild-type plants.

Nitrate is the major source of nitrogen for higher plants, with nitrate reductase catalyzing the first step in its assimilation. However, lettuce and other leafy vegetables such as chicory, rocket, and spinach, provide most of the nitrogen intake in typical diets (De Martin and Restani, 2003). Lettuce often accumulates nitrate to concentrations that exceed the maximum permitted concentration. Indeed, nitrate concentration is one of several parameters that govern the marketability of the crop, especially in winter, especially when plants accumulate nitrate because of low light conditions. In experiments to reduce nitrate accumulation in lettuce, Curtis *et al.* (1999a) introduced the *nia2* cDNA for nitrate reductase from tobacco driven by the 35S promoter into the cv. Evola. Unfortunately, none of the transgenic plants exhibited a reduction in nitrate content compared to the wild-type plants at harvest, although plants with nitrate concentrations slightly less than those of wild-type plants were observed during cultivation. Subsequently, Dubois *et al.* (2005) investigated nitrate accumulation in the cv. Jessy using a similar 35S::*nia2* construct. They again concluded that none of the plants carrying the transgene exhibited a reduction in nitrate accumulation, although the transgene was expressed. Transgene-specific silencing extended to the homologous endogenous nitrate reductase mRNA (messenger RNA) resulting in chlorosis and eventual death of the transgenic plants. Clearly, this approach for reducing nitrate accumulation has difficulties.

4.1.2.7 Extending postharvest shelf life

Lettuce and other leafy vegetables deteriorate rapidly after harvest. Consequently, delaying leaf senescence is an important target for genetic manipulation. Curtis *et al.* (1999b) introduced the *T-cyt* gene (synonym *ipt*, *tmr* or gene 4) coding for isopentenyl phosphotransferase, which is involved in cytokinin biosynthesis, from the T-DNA of *A. tumefaciens* on the binary vector pMOG23 into the lettuce cv. Saladin. Transgenic plants were phenotypically normal following transfer to the

glasshouse, set viable seed, and had increased cytokinin and chlorophyll contents in their leaves compared to nontransformed plants. Such results indicated the possibility of delaying senescence in lettuce, possibly reducing the requirement for postharvest controlled environmental conditions to prolong the shelf life of harvested plants.

In subsequent, more elaborate investigations, the *ipt* gene driven by the senescence-specific promoter *SAG12* from *A. thaliana* (*pSAG12-IPT*) was introduced into the lettuce cv. Evola. Plants homozygous for the transgene exhibited significantly delayed postharvest leaf senescence (McCabe *et al.*, 2001). Importantly, the transgene was activated only during senescence, particularly when the latter process commenced in the outer (lower) leaves, initiating cytokinin biosynthesis. The latter then inhibited leaf senescence, simultaneously attenuating activity of the *pSAG12-IPT* gene, preventing cytokinin overproduction. Heads of transgenic plants retained chlorophyll for up to 7 days longer in their outer leaves after harvest compared to leaves of nontransformed plants. Mature plants were morphologically normal when harvested, with no significant differences in head diameter or fresh weight of leaves or roots compared to their nontransformed counterparts. In later experiments, the metabolites synthesized by *pSAG12-IPT* transformed plants were compared with those metabolites synthesized by nontransformed plants using atmospheric pressure chemical ionization-mass spectrometry (APCI-MS) and linked gas chromatography/atmospheric pressure chemical ionization/electron ionization mass spectrometry (GC-APCI/EI-MS) (Garratt *et al.*, 2005). During storage, heads of transgenic plants showed a threefold increase in the concentrations of acetaldehyde, ethanol, and dimethyl sulfide, increase in the latter compound being paralleled by an accumulation of reactive oxygen species. Such investigations emphasize the importance of detailed metabolite profiling of plants following transgene insertion, as the integration of a gene to modify one or more traits may affect other biosynthetic pathways.

Attention has also been given to the effects of ethylene on leaf senescence, since it influences fruit ripening and senescence. Thus, in the study by Kim and Botella (2004), cotyledons from 6-day-old seedlings of the cvs. LE126 and Seagreen were transformed by *A. tumefaciens*

carrying a construct with the ethylene mutant receptor gene *etr1-1*, under the control of the same promoter, *SAG12*, as used by McCabe *et al.* (2001). Expression of *etr1-1* induced root formation from 34% of the explants with a delay in callus and shoot initiation. Only a limited number of explants regenerated shoots, indicating that ethylene insensitivity conferred by *etr1-1* modifies shoot regeneration. Additional studies are required to characterize fully the long-term effects of ethylene on leaf senescence in lettuce.

4.1.2.8 Synthesis of high value recombinant proteins

The synthesis of pharmaceutically important compounds in plants through recombinant-DNA technology has important medical and economic implications, with plant-made oral vaccines having the potential to overcome many of the limitations of traditional vaccines. For example, Webster *et al.* (2006) expressed a measles virus hemagglutinin protein in transgenic lettuce in efforts to produce a vaccine, while Kim *et al.* (2006a) also produced a cholera toxin B subunit in lettuce following *Agrobacterium*-mediated transformation of cotyledons. Western blot analysis and enzyme-linked immunosorbent assay quantification provided an estimated 48 ng of toxin B protein per 20 µg of total soluble protein, amounting to 0.24% of the latter. The generation of transgenic plants has also been directed to the oral delivery of recombinant proteins to animals. Thus, Legocki *et al.* (2005) showed that transgenic lettuce expressing the E2 glycoprotein of Classical Swine Fever Virus or cysteine protease from *Fasciola hepatica*, induced immunoprotective properties in laboratory mice. Such experiments provide a basis for the transformation of plants exploited more routinely in the raw state for animal feeds, such as grasses, root crops, and members of the Brassicaceae.

Negrrouk *et al.* (2005) developed a simple system to produce recombinant antibodies in lettuce and, since the procedure negates the requirement for plant growth facilities, it should be applicable to any cultivar. Mature harvested heads were dipped in a suspension of *A. tumefaciens* strain C58C1 carrying the appropriate construct, before vacuum infiltration. Subsequently, the heads were

rinsed in water and incubated on wet paper in closed transparent boxes at 20–26 °C, with a 16 h photoperiod, for 3–4 days. Leaves were homogenized and protein extracted to yield 20–80 mg kg⁻¹ fresh weight of leaf tissue of humanized IgG1 k antitissue factor antibody (hOAT) in less than 7 days. This simple procedure should be amenable to scale-up for a range of products. Joh and VanderGheynst (2006) also emphasized the merits of agroinfiltration of plant tissues for transient gene expression as an alternative to stable transformation of target plants. In fact, the correct combination of *Agrobacterium* and plant tissues can result in the synthesis of more recombinant protein compared to that produced in stably transformed plants, as reported for lettuce by Wroblewski *et al.* (2005). In studies from the same group, Joh *et al.* (2005) also noted that different leaf tissues had different GUS activities, gene expression also being influenced by leaf pigmentation.

4.1.2.9 Male sterility

Male-sterile plants are important as pollen recipients for hybrid plant production by sexual hybridization. In experiments to induce male sterility in lettuce, a pathogenesis-related β -1,3-glucanase gene linked to a tapetum-specific promoter, *A9*, was cloned into the binary vector pBIN19 and the latter introduced into *A. tumefaciens* carrying pGV2260, prior to transformation of the cv. Lake Nyah (Curtis *et al.*, 1996b). Transgene expression resulted in dissolution of the callose wall of developing microspores, inhibiting pollen grain development, resulting in male sterility. This, or a similar approach, may eliminate the need to remove pollen from the stigmatic surface of recipient plants to avoid self-pollination, prior to application of donor pollen.

4.2 Introduction of Genes into Chicory

4.2.1 Modification of plant morphology and physiology

Currently, there are few reports of the introduction and expression of genes in chicory. An early report of genetic manipulation involved the

transformation of root and pedicel explants of the cv. Hybrid Flash by *A. rhizogenes* strains A4RSII and 8169. Plants regenerated from roots transformed by strain A4SRII changed from biennial to annual flowering, and exhibited stunted growth, wrinkled leaves, reduced development of taproots, but proliferic development of lateral roots (Sun *et al.*, 1991). Although the plants still had a requirement for an inductive period to promote flowering, a vernalization period was unnecessary. The phenotypic alteration of growth habit in these transgenic plants was at least partially associated with expression of the *rol A-C* genes on the Ri T-DNA, these genes being shown to have a similar effect on flowering in other biennial plants, such as carrot.

Following the report by Sun *et al.* (1991), Limami *et al.* (1998) investigated the switch from biennial to annual flowering. Backcrossing of transformed with nontransformed plants produced a line that retained annual flowering in the absence of other phenotypic abnormalities. Molecular analyses indicated that the annual habit was associated with a truncated T-DNA inserted into the plant genome. When transgenic plants were harvested at the end of a 5-month period, the inulin concentration in their roots was found to be the same as that in nontransformed plants, ranging from 71% to 75% of the root dry weight. However, at the end of the vegetative period, the free fructose content increased 8- to 10-fold in the roots of transformed plants because of increased inulin hydrolysis in the transgenic plants at this time. In contrast to the situation in nontransformed plants, chicon induction in transgenic plants did not require a vernalization period of 0–2 °C for 14 days.

Vijn *et al.* (1997) exploited the transformation protocol of Vermeulen *et al.* (1992) to introduce a fructan:fructan 6G-fructosyltransferase (6G-FFT) from onion into chicory. The results of these experiments showed that it was possible to modify the type of fructan synthesized in a fructan-producing plant. Transgenic plants were found to accumulate the fructan encoded by the transgene, together with endogenous fructans. Genes, such as *gus* and *gfp* (green fluorescent protein), are useful as reporters as their expression can be monitored at all stages of cellular differentiation. For example, in studying the origin of shoots from cultured leaf explants, Pieron and Watillon (2001)

transformed chicory with a 23 kb fragment of an apple calmodulin promoter fused to the coding sequence of the *uidA* (*gus*) gene. The origin and development of shoots were readily detected by the indigo staining of cells expressing the *gus* gene.

4.2.2 Herbicide tolerance

The introduction of herbicide tolerance into chicory was addressed using a mutant acetolactate synthase gene (*csr1-1*) from *Arabidopsis*, which conferred resistance to the herbicide chlorsulfuron (Vermeulen *et al.*, 1992). Leaf discs from 8-week-old plants were inoculated with an overnight culture of *A. tumefaciens* strain LBA4404 harboring pGH6, the latter carrying the gene of interest and the *neo* gene (from pBIN19) conferring kanamycin resistance on transformed plant cells. Leaf discs were transferred after co-cultivation with bacteria to semi-solid MS-based shoot induction medium, shoot regeneration occurring after 12–15 days in the presence of 0.1 mg l^{-1} IAA and 1 mg l^{-1} BAP. Transformed shoots were selected, micropropagated, and acclimatized to glasshouse conditions; flowering was induced by vernalizing the plants for 2 months at 6°C prior to self-pollination. Seeds germinated *in vitro* and seedlings were resistant to both kanamycin and chlorsulfuron.

4.2.3 Assessments of the response of explants to *Agrobacterium* inoculation

In studies to increase transgenic plant regeneration, taproots, leaf discs, and cotyledons, the latter from etiolated seedlings of the Witloof cv. Flash, were transformed using *A. tumefaciens* strains carrying either pGSGLUC1 or pTDE4, encoding *nptII* and *uidA* (*gus*) genes under different promoters (Abid *et al.*, 1995). Genes on pGSGLUC1 were driven by the TR1' and TR2' promoters, while on pTDE4 the *uidA* and *nptII* genes were controlled by the CaMV 35S and *nos* promoters, respectively. The suspension of *Agrobacterium* for inoculating the explants was cultured in medium containing $100 \mu\text{M}$ acetosyringone. The culture medium used was crucial

in these experiments. Taproots were incubated on Heller's (1953) medium containing 75 mg l^{-1} kanamycin. Leaves and cotyledons were wounded manually prior to bacterial inoculation and before culture on half-strength MS-based medium in the presence of 0.1 mg l^{-1} BAP for 2 days followed by selection with $75 \mu\text{g ml}^{-1}$ kanamycin. After 2–3 weeks, shoots were transferred to agar-solidified Heller's medium containing 10 g l^{-1} sucrose and $75 \mu\text{g ml}^{-1}$ kanamycin to induce roots. Cotyledon explants were the most responsive to *Agrobacterium* inoculation. As shoots developed rapidly from taproots, it was necessary to maintain root explants on a medium that was relatively poor in nutrients to prevent the production of chimaeric shoots. Leaf and cotyledon tissues required a more nutrient rich medium for shoot initiation. In these experiments, kanamycin selection did not inhibit shoot regeneration from culture explants, although in earlier work, Vermeulen *et al.* (1992) demonstrated that kanamycin inhibited shoot regeneration.

Buds have also been used in transformation studies of chicory (Frulleux *et al.*, 1997). Explants of the cvs. Hicor, Inula, Tilda, VBF, VBG, and VAX were cultured on semi-solid B5-based medium containing 0.9 mM BAP. *A. tumefaciens* strain GV2260:35SGUSINT carrying the *gus* gene was used in transient expression studies. *Agrobacterium* strain EHA101 carrying pGV1531 with *nos-nptII* and CaMV 35S-*uidA* genes was used for stable transformation. Shoot buds (each 2–3 mm in size) were inoculated with an overnight bacterial suspension, before co-cultivation with the bacteria for 2 days. Explants were washed with a solution of carbenicillin at 500 mg l^{-1} before culture with the same concentration of the antibiotic to eliminate bacteria. Kanamycin at 100 mg l^{-1} was used for initial selection the concentration being increased to 200 mg l^{-1} after 4 weeks. Shoots were exposed to this selection pressure for 4 months, before being rooted on 0.98 mM IBA. Leaf discs excised from putatively transformed plants regenerated shoots on kanamycin-containing medium, while Southern analysis confirmed the presence of the *nptII* gene in kanamycin resistant plants. Transformed plants were self-pollinated after vernalization treatment (6°C); segregation analysis showed a 3:1 ratio of kanamycin resistant to sensitive seedlings.

More recent investigations have used *A. rhizogenes* for gene delivery. Bais *et al.* (2001) inoculated hypocotyls from 2- to 10-day-old seedlings of the chicory cv. Lucknow Local with strains LMG-150, A20/83, and AZ/83 of mannopine-type bacteria. After co-cultivation on MS-based medium for 3 days, explants were exposed to 500 mg l⁻¹ of carbenicillin, with subculture to new medium every 3 days. Roots that developed were transferred to liquid MS-based medium in the dark on a rotary shaker to obtain axenic cultures of transformed “hairy” roots. A bacterial concentration of 10⁸ cells ml⁻¹ was optimal for inoculation, with most explants producing transformed roots following inoculation with strain LMG-150. However, this response declined with explants taken from seedlings more than 2 days old. Shoots were induced from transformed roots on MS-based medium with 4.0 mg l⁻¹ BAP and 1.0 mg l⁻¹ NAA, and were micropropagated on medium with 0.5 mg l⁻¹ of GA₃, 2.0 mg l⁻¹ 2,ip, and 0–50 mM putrescine. The latter at 40 mM was optimal for shoot induction and stimulated flowering *in vitro* of regenerated shoots. Putrescine could be replaced by silver nitrate at 40 μM to stimulate shoot multiplication. In their subsequent investigation, Bais and Ravishankar (2003) showed IAA and IAA oxidase to be more in roots induced by strain LMG-150, with IAA, IAA oxidase, coumarin, and biomass being stimulated by treating cultured roots with putrescine at 1.5 mM.

4.3 Spinach

4.3.1 Transformation by *Agrobacterium*

The transformation of spinach by *Agrobacterium* is considerably more difficult to achieve compared to lettuce and chicory and is highly cultivar dependent. Al-Khayri (1995) transformed spinach using an established culture system (Al-Khayri *et al.*, 1991). They inoculated leaf discs from 3-month-old plants, hypocotyl segments from 14-day-old seedlings and cell suspensions from leaf-derived callus of the cv. High Pack, with *A. tumefaciens* strain A208 carrying the disarmed binary vector pMON9749, the latter with the CaMV 35S-*gus* and *nos-nptII* genes, and a gene for spectinomycin

resistance. Leaf explants and hypocotyl segments were co-cultivated with *Agrobacterium* on MS-based medium supplemented with 2.0 mg l⁻¹ kinetin and 0.5 mg l⁻¹ 2,4-D to induce callus. Later, the explants were transferred to medium with 100 mg l⁻¹ cefotaxime, 100 mg l⁻¹ carbenicillin, and 50 mg l⁻¹ kanamycin to select transformed callus and transgenic shoots. Callus formed in the dark on 3–8% of the leaf explants and on 4–10% of the hypocotyl segments. Cell suspensions were inoculated with 50–200 μl aliquots of an overnight bacterial suspension, washed 2 days later with liquid MS-based medium to remove the bacteria and incubated in liquid medium with antibiotics, including kanamycin, for 21 days in the light. Cells were plated onto kanamycin-containing selection medium for 21 days in the dark, prior to transfer to semi-solid shoot regeneration medium. Most cells in the suspension were GUS positive after incubation with agrobacteria. Consequently, it was argued that cell suspensions provided the optimum experimental system for spinach transformation. Kanamycin resistant plants transferred to the glasshouse were morphologically normal.

Three publications appeared in 1997. Knoll *et al.* (1997) described shoot regeneration using root explants as the starting material. Roots that were the source of the explants were induced on cultured seedling hypocotyl segments of the cvs. Longstanding Round and RS No. E, this regeneration system being used for transformation. *A. tumefaciens* strain 0065 and the supervirulent strain 1065, carrying the binary vector pMOG23 with *nptII* and *gus* genes, were used for inoculation. Explants were immersed in a 1:10 (v:v) dilution of an overnight culture for 2 s or in a 1:1 dilution of the bacterium for 10 min. Inoculated explants were cocultivated for 2 days with agrobacteria followed by transfer to Nitsch and Nitsch (1969) medium supplemented with 100 mg l⁻¹ cefotaxime, 100 mg l⁻¹ carbenicillin, and 50 mg l⁻¹ kanamycin sulfate for selection. Although transgenic plants were not obtained, histochemical studies showed shoot buds exhibiting GUS activity 56 days after bacterial inoculation on explants taken from roots that had been cultured for 20 months prior to inoculation with strain 1065.

Daniels *et al.* (1997) targeted leaf and cotyledon explants using *A. tumefaciens* strain AGLO

carrying a binary vector with the *nptII* gene and the *gfp* gene for green fluorescent protein. The *gfp* gene with the CaMV 35S promoter, was designed to target GFP to the endoplasmic reticulum. Explants were inoculated with overnight bacterial cultures prior to culture in the dark at 24 °C for 84 days on callus induction medium (Al-Khayri *et al.*, 1991). Stable gene expression was reported in cultured plant tissues 21 weeks from the initiation of the experiment. A bacterial suspension of optical density 1.0 resulted in a higher percentage of calli expressing *gfp* than a more dilute bacterial suspension with an optical density of 0.3. Although transformed callus was obtained from leaf explants, cotyledon explants could not be transformed using the same approach.

The spinach cvs. Fall Green and High Pack were targeted by Yang *et al.* (1997) in attempts to introduce virus resistance into the latter cultivar. *A. tumefaciens* strain LBA4404 was used carrying the binary vector pB1121, with the coat protein gene of the CMV isolates, SP103, and SP104, replacing the *gus* gene of the original construct. Leaf strips and hypocotyl segments from 6-week-old plants were inoculated with overnight cultures of *Agrobacterium* to which 0.05 mM acetosyringone had been added 4 h before explant inoculation. Explants were transferred to callus induction medium (Al-Khayri *et al.*, 1991) after 2 days of co-cultivation with bacteria on semi-solid MS-based medium. The latter was supplemented with 237 µM carbenicillin, 209 µM cefotaxime, and 86 µM kanamycin, with transfer of cultures to new medium every 4 weeks over a period of 12 weeks. Calli were then transferred to shoot regeneration and root induction media (Al-Khayri *et al.*, 1991), both supplemented with cefotaxime and carbenicillin, in the light. Shoots were induced on both leaf and hypocotyl-derived calli of the cv. High Pack. Shoots were not obtained from the cv. Fall Green. In contrast, 12% of the regenerated plants of the cv. High Pack carried the CMV coat protein gene, the latter being detected using the PCR, with Southern and Northern blots confirming the presence of the gene and its protein product in transgenic plants.

Zhang and Zeevaart (1999) reported a rapid and efficient procedure for generating transgenic spinach plants by inoculating cotyledons excised from 5-day-old seedlings of the cv. Longstanding Bloomsdale Dark Green. As reported by Yang

et al. (1997), *A. tumefaciens* strain LBA4404 pB1121 was used, in which the CaMV 35S-*gus* region of the original construct was replaced by 35S-*smgfp*, a gene encoding a more soluble version of a codon-modified green fluorescent protein. The rationale for using the *gfp* gene as a marker was based on the earlier studies of Yang *et al.* (1997) and Daniels *et al.* (1997). *Agrobacterium* was cultured overnight with 0.2 mM acetosyringone, before being diluted 1:10 by volume with new medium and culture for a further 48 h prior to inoculating explants. Co-culture with *agrobacteria* was on MS-based medium with 1.0 mg l⁻¹ BAP and 0.4 mg l⁻¹ NAA, prior to transfer to selection medium containing 100 mg l⁻¹ cefotaxime, 200 mg l⁻¹ carbenicillin, and 50 mg l⁻¹ kanamycin. Eighty-six percent of the inoculated explants cultured in the presence of kanamycin regenerated shoots. The latter were excised from the parental explants and were immersed in liquid MS-based medium supplemented with 20 mg l⁻¹ IBA for 2 h, before transfer to semi-solid MS-based medium containing 1.0 mg l⁻¹ IBA for rooting. Kanamycin resistant plants were hybridized with wild-type plants, as the dioecious nature of spinach precluded self-fertilization. Seeds were germinated on selection medium containing kanamycin sulfate at 50 mg l⁻¹ with a 1:1 segregation of resistant to susceptible T₁ generation seedling; seedlings of the T₂ generation were found to segregate 3:1 (resistant to susceptible), suggesting that the *nptII* gene was inherited in a Mendelian fashion. Northern and Southern analyses established the transgenic nature of the T₂ generation plants. This investigation by Zhang and Zeevaart (1999) represented a major advance in spinach transformation.

The limited reports on spinach transformation probably reflect the difficulty of inserting genes into this leafy vegetable. The age and source of explants that are inoculated with *Agrobacterium* are critical in maximizing transformation. In attempts to stimulate transformation, Daniels *et al.* (1997) supplemented the medium for bacterial inoculation with the surfactant Pluronic F-68, this increasing transformation from 5.1% to 19.7%. Dilution of the *Agrobacterium* suspension and the time of inoculation are important, Knoll *et al.* (1997) reporting that a 1:10 (v:v) dilution of an overnight *Agrobacterium* culture stimulated transformation compared with an

undiluted culture, or a bacterial suspension diluted 1:1 by volume as the inoculum. *Agrobacteria* used for inoculation of plant tissues are also important, supervirulent strains, such as 1065, giving the highest rates of transformation.

4.3.2 Viral vectors for gene introduction into spinach

As in lettuce, investigations have been initiated to induce spinach to synthesize pharmaceutically important products. In circumventing the requirement for *Agrobacterium*-mediated gene delivery, Karasev *et al.* (2005) cloned a HIV-1 *tat* gene into a tobacco mosaic virus based vector in studies to develop a preventative AIDS vaccine. The HIV-1 *tat* protein has been exploited as a possible vaccine candidate because of its broad nonspecific action, with the potential of delivery through the mucosal route following *tat* expression in an edible plant. Spinach plants inoculated with *tat*-producing constructs synthesized up to 300 µg of *tat* per gram of leaf tissue. The attraction of such a system is its rapidity, since plants can be harvested for use within 7–14 days of inoculation with the viral constructs.

5. PRESENT AND FUTURE STRATEGIES FOR LEAFY VEGETABLES

5.1 Plastid Transformation—The Way Ahead?

Whilst genetic manipulation studies have focused, in general, on the introduction of genes into the nucleus, interest in plastid transformation has gained momentum, since it offers advantages compared to nuclear transformation. Such advantages of plastid transformation include lack of gene silencing because of the ability to integrate genes into specific intergenic regions of the plastome, and the potential for high foreign gene expression. Transgene containment is also an important issue because of the maternal inheritance of cytoplasmic genomes (Daniell *et al.*, 2002; Maliga, 2003; Skarjinskaia *et al.*, 2003). In the first report of plastid transformation in lettuce, Lelivelt *et al.* (2005) used PEG-induced DNA uptake into isolated leaf protoplasts of the

lettuce cv. Flora to generate fertile, homoplasmic plants. The vector used for transformation targeted genes to the *trnA-trnI* intergenic region of the lettuce plastome, with the *aadA* gene for resistance to spectinomycin as a selectable marker. Spectinomycin resistance and heterologous gene transcription were demonstrated in first seed generation transgenic (T₁) plants, following self-pollination of primary regenerants. Crossing of transgenic plants with male sterile wild-type lettuce confirmed that antibiotic resistance was not transmitted by pollen. Using a similar strategy, Kanamoto *et al.* (2006) reported transplastomic plants of the lettuce cv. Cisco, the *aadA* gene being inserted between the *rbcL* and *accD* genes of the lettuce genome. Both Lelivelt *et al.* (2005) and Kanamoto *et al.* (2006) discussed the potential of plastid transformation for the production and delivery of edible human therapeutic proteins. Plastid transformation is also an important option for chicory and spinach and it seems likely that this technology will be developed for these leafy vegetables in due course.

5.2 Risks and Consumer Concerns

Maintaining adequate supplies of leafy vegetables is an ongoing procedure in order to satisfy consumer demands. For example, the market for lettuce has increased in the last two decades, accompanied in some cases, by a change in the range of cultivars being grown, especially for processed mixed salad. Since the viability of lettuce seed is limited when stored at room temperature, experiments have been conducted on the longevity of cryogenically stored seeds (Walters *et al.*, 2004). Cryogenic storage prolonged seed viability giving estimated half-lives in excess of 500 and 3400 years for freshly harvested seed stored in the vapor and liquid phases, respectively, of liquid nitrogen. This approach may be important in the future long-term conservation of elite lines not only of lettuce but also of other leafy vegetables.

All leafy vegetables deteriorate rapidly following harvest, with a considerable investment of effort to maintain quality and shelf life of cut material. Harvesting increases respiration, stimulating deterioration, with increase in the synthesis of phenylalanine ammonia lyase and phenolic compounds, such as chlorogenic acid that

cause tissue browning (Kang and Saltveit, 2003). Exposing cut heads and leaves of iceberg lettuce to 1-methylcyclopropene decreased the accumulation of phenolic compounds and tissue discoloration (Saltveit, 2004), while wound-induced accumulation of phenolic compounds and browning in the Romaine lettuce cv. Longifolia was reduced by exposure to n-alcohols (Choi *et al.*, 2005). Ragaert *et al.* (2006) reported the volatile metabolites generated by bacteria (*Pantoea agglomerans* and *Rahnella aquatilis*) and spoilage yeasts (*Pichia fermentans* and *Cryptococcus laurentii*) in lettuce.

Although leafy vegetables, as consumed in the raw state, make a significant contribution to a healthy diet, there is a need to reduce health risks from such uncooked vegetables. Consequently, attempts have been made to reduce microbial activity on the surface of harvested lettuce leaves, using, for example, ozone in combination with chlorine, and ozonated water to reduce surface microbes (Garcia *et al.*, 2003; Beltrán *et al.*, 2005) whilst retaining sensorial qualities. Washing with calcium lactate (Martin-Diana *et al.*, 2005; Rico *et al.*, 2006), exposure to chlorine dioxide gas (Lee *et al.*, 2004), and chlorine and peroxyacetic acid, as sanitizers (Beuchat *et al.*, 2004) have been investigated in destroying surface contaminants such as *Listeria monocytogenes*, *Escherichia coli* 0157:H7, *Salmonella typhimurium*, and *Enterobacter sakazakii* (Kim *et al.*, 2006b). Calcium lactate maintained quality better than treatment with ozone or ozone combined with calcium lactate (Rico *et al.*, 2006). Similar investigations have been performed on the effect of different sanitizers on the microbial, nutritional, and sensory qualities of leaves of rocket (*Diplotaxis tenuifolia*; Martinez-Sanchez *et al.*, 2006).

Exposure of lettuce to ultraviolet radiation could reduce microbial loading without affecting quality, as in the cv. Lollo Rosso (Allende and Artés, 2003; Yaun *et al.*, 2004; Gómez-López *et al.*, 2005). The atmosphere within the packaging of harvested material, the time of packaging following cutting, and the type of packaging, also influence the shelf life of the harvested produce (Kim *et al.*, 2005a, b; Del Nobile *et al.*, 2006). An interesting paper by Song *et al.* (2006) demonstrated that the method of irrigation of plants before harvest influences the microbial population on their leaves, subsurface drip irrigation having the potential to reduce

health risks of lettuce. Park *et al.* (2006) developed multiplex PCR assays to detect pathogens in leafy vegetables, since robust procedures are fundamental in detecting food-based pathogens.

6. CONCLUDING REMARKS

Globally, leafy vegetables are of considerable nutritional and economic importance, with lettuce and spinach being major sources of carotenoids, particularly lutein and zeaxanthin (Lucarini *et al.*, 2006). Consequently, it is not surprising that considerable effort will be focused on maximizing yield and durability of these crops through both conventional breeding and genetic manipulation approaches. Molecular procedures will facilitate the selection of germplasm for incorporation into breeding programs. Shoot regeneration from explants, tissues, and isolated protoplasts, facilitates the application of *in vitro*-based technologies to underpin conventional breeding. Whilst gene manipulation procedures have been based mainly upon transformation, somatic hybridization by protoplast fusion should not be ignored, since this provides a means of mobilizing genes without the need for sophisticated recombinant-DNA technology. Where transformation is exploited for cultivar improvement, long-term transgene expression may be compromised in certain lettuce cultivars. This issue needs to be addressed; the use of appropriate constructs and transformation protocols should reduce the incidence of this problem. Some cultivars of chicory are amenable to transformation. However, in general, transformation is not readily applicable to spinach at the present time. In both spinach and chicory, lack of protoplast-to-plant systems precludes the use of somatic hybridization for gene transfer, at least in the immediate future. Conventional breeding will continue to play a central role in the improvement of existing cultivars for traits, such as resistance to tipburn (Hayes, 2006) and in the development of new cultivars of leafy vegetables. In addition, it is likely that producers will become more long-term dependent upon somatic cell approaches in order to meet consumer demands in terms of the availability of new cultivars with improved nutritional quality, enhanced shelf life, and maximum food safety.

1. INTRODUCTION

1.1 History, Origin, and Distribution

Sugarcane is a large grass of the genus *Saccharum*, tribe Andropogoneae, family Poaceae. Modern sugarcane (*Saccharum* spp.) cultivars are interspecific hybrids derived from a hybridization process involving *Saccharum officinarum* (or “noble cane”) and *Saccharum spontaneum* (wild cane), followed by a series of backcrosses to the noble parent (Daniels and Roach, 1987).

The earliest known historical record of sugarcane and sugar is from Indian writings from 3000 to 3400 years ago. The generic name for sugarcane, *Saccharum*, originated from the Indian Sanskrit term “*sharkara*” for the crude sugary product obtained from the honey reeds. Dispersal of Indian sugarcane westward seems to have occurred during the first millennium BC. Soldiers of Alexander the Great are known to have carried it to Europe from India about 325 BC. Later, Greek and Roman

writers were familiar with the concept of the Indian honey reed and its “honey” (sugar) product. The early history of sugarcane is covered by a number of authors, including Deer (1949) and Barnes (1964).

The origin of sugarcane is a complex question that is best discussed in relation to its taxonomy and distribution in Southeast Asia, the Indonesian Archipelago, and New Guinea. Different species likely originated in various locations with *S. officinarum* and *Saccharum robustum* in New Guinea, *Saccharum barberi* in India, and *Saccharum sinense* in China. Dispersal of *S. officinarum* over a period of thousands of years is believed to have occurred both into the Pacific Ocean area, and along the island chain into Asia, whilst the thinner Indian canes were developed and cultivated in the North India/South China region.

Initially, pieces of cane stalk would have been chewed to express the sweet juice, and chewing canes still provide a conveniently packaged form of energy food in many cultures. Juice extraction

from the stalk, and concentrating it by drying or heating to produce a crude sugary product, must have been developed in a rudimentary form at least 3000 years ago. The art of sugar manufacture took longer to develop, probably in India and perhaps less than 2000 years ago. Deer (1949) considered that Nestorian Christian monks at the mouth of the Euphrates river were the first to refine the crude raw product into a form of “white” sugar about 450 AD.

The Mediterranean sugar industry was the first major one in Europe, and began about the time of the Arabian conquest of Egypt in 640 AD. They spread it across North Africa and into Spain by 750 AD, where it was important for many years, with 30 000 ha under cane by 1150 AD. By the early 1500s AD, cane was carried by the Spanish to the Caribbean and the Americas, and by the Portuguese to West Africa and Brazil. And so the worldwide sugarcane industry was born.

Prior to the 20th century, the world sugarcane industry was dependent on the noble canes (*S. officinarum*) and the cane from India and China (*S. barberi* and *S. sinense*, respectively) (Sreenivasan *et al.*, 1987). These canes were characterized by high sucrose levels and low fiber contents, but were susceptible to several pests and diseases, notably sereh disease (Arceneaux, 1965). Sugarcane breeding and selection became a directed, ongoing process following the observation in 1858 that sugarcane panicles produce viable seed (Stevenson, 1965). The Dutch established a breeding and selection program in 1888 in Java to incorporate the disease resistance, hardiness, and tillering capacity of *S. spontaneum* into *S. officinarum* germplasm. Interspecific crosses were made between *S. officinarum* and the wild *S. spontaneum* (which was resistant to sereh) (Stevenson, 1965). The resultant hybrids were continually backcrossed to *S. officinarum* in a process called nobilization (Stevenson, 1965). This effort resulted in the release of the first of the nobilized hybrid cane cultivars, POJ2725 and POJ2878 in 1921. These two early cultivars served as the foundation in the pedigree of nearly all locally developed and adapted modern sugarcane cultivars worldwide (Moore, 2005). Nobilization became established as a method of retaining the desirable qualities of *S. officinarum*, retaining the hardiness and disease resistance of *S. spontaneum*, while diluting the negative effects of wild germplasm (Berding and Roach, 1987).

Currently, sugarcane is widely grown for sugar production in many tropical and subtropical countries (with a minimum of 600 mm of annual rainfall) in South, Central, and North America, the Caribbean, Africa and adjacent islands, Southern Asia and Australasia.

1.2 Evolution, Taxonomy, Cytological Features, and Genome Size

Mukherjee (1957) coined the term “*Saccharum* complex” to describe a large, closely related genera (*Erianthus* sect *Rhipidium*, *Miscanthus*, *Sclerostachya*, *Narenga*), which are considered to be involved in the evolution of cultivated species of *Saccharum*. The phylogenetic relationships within the *Saccharum* complex have been debated for many years (Daniels and Roach, 1987; Irvine, 1999). A long discourse on how the various species may have evolved is provided by Daniels and Roach (1987).

Sugarcane technologists consider six species to be important as progenitor species in the origin of modern commercial hybrids (*Saccharum* spp.). These six species (listed below) are distinguishable on the basis of sugar content, thickness of stalk, floral characteristics, chromosome number and epidermal hairs. The first four in the list below are in cultivation, while the last two (*S. spontaneum* and *S. robustum*) are wild species growing in southern Asia and New Guinea.

- *S. officinarum* L.: sweet, juicy, thick stalk garden cane, initially in New Guinea
- *S. barberi* Jesw.: sweet, thin stalk Indian canes
- *S. sinense* Roxb.: sweet, thin stalk Chinese canes
- *S. edule* Hassk.: edible inflorescence garden cane, New Guinea, Melanesia
- *S. spontaneum* L.: very thin, hardy wild canes, low sugar, New Guinea and southern Asia
- *S. robustum* Brandes & Jeswiet ex Grassl: tall, harder, thick stalk wild canes, a little juice and sugar, New Guinea and eastern Indonesia

Modern commercial sugarcane cultivars are highly heterozygous, complex polyploid, and aneuploid hybrids, often with four of the above species of *Saccharum* in their ancestry. Cytological studies showed that nobilization is characterized by asymmetric chromosome transmission (Bremer, 1961). In a cross between *S. officinarum* ($2n = 80$) as the female parent and

S. spontaneum ($2n = 40\text{--}128$) as the male parent, *S. officinarum* generally transmits two haploid chromosome sets while *S. spontaneum* transmits one. This $2n + n$ transmission is continued up to the second backcross. A consequence of this is that modern cultivars have chromosome numbers ranging from $2n = 99\text{--}130$ (Bremer, 1961). In addition, commercial sugarcane cultivars have complex polyploid (10–12 copies of the genome) and aneuploid (100–120 chromosomes) genomes. In polyploids such as sugarcane, the haploid chromosome number (1C value = n) is not the same as the monoploid number (= x) (Butterfield *et al.*, 2001). The monoploid genome size for *S. officinarum* ($x = 10$) is approximately 926 Mbp (mega base pair), and for *S. spontaneum* ($x = 8$) 760 Mbp (Butterfield *et al.*, 2001). This base genome number is roughly double the monoploid genome size of rice (415 Mbp) and similar to that of *Sorghum bicolor* Moench (760 Mbp) (Butterfield *et al.*, 2001).

1.3 Economic Importance: Production, Utilities, Economic Attributes, and Industrial Uses

Sugarcane is cultivated for its high rate of sucrose accumulation, ease of propagation via vegetative stem cuttings and multiple harvests from a single planting. It is a principal crop in tropical and subtropical regions, with a production estimate of over 1.3 million metric tons of sucrose per annum. It provides approximately 70% of the world's sugar (FAO, 2006).

Sugarcane has long been recognized as one of the most efficient crops in terms of converting solar energy into biomass (Alexander, 1973). It is one of the most effective photosynthesizers in the plant kingdom, able to convert 2% of incident solar radiation into plant biomass. It is the second largest contributor (10–12%) of dietary carbohydrate to humans after the cereals. Sugar processing meets the needs of both high-income consumers (e.g., refined white and specialty sugars) and low-income domestic consumers (e.g., the production of jaggery in India or panela in Colombia, where cane juice is boiled to make cakes of brown sugar). By-products of sugar milling such as bagasse, molasses, furfural, furfuryl alcohol, dextran, and diacetyl (O'Reilly, 1998) have several uses. For example, bagasse (a fibrous residue after sugar

extraction) can be used to fuel boilers in the sugar mills, to generate electricity for the local power grid, to manufacture paper, and as an animal feed. Molasses are used in syrups and animal feed and as a substrate for ethanol production.

Sugarcane is considered as a critical component of our bioenergy future as: (i) sugarcane is already used in the production of ethanol, produced by fermentation and distillation of sugars. Currently, Brazil is the world's largest producer of sugarcane ethanol (Moreira, 2000). Ethanol can be blended with gasoline (gasohol) or diesel (biodiesel or dieselhol); (ii) production of energy, such as ethanol, from sugars is more efficient than production from grains, in both cost for joule produced and energy input/output efficiency. For each unit of fossil energy input to the sugarcane agro-industrial system, nine units of renewable energy output (ethanol plus surplus bagasse) result, compared to less than 2 units resulting from grains, such as maize; and (iii) sugarcane is ranked first among all other crops for biomass production (FAO: <http://www.fao.org>; Moreira, 2006). As a perennial crop, it has more advantages for biofuels production than annual crops. It is more efficient at solar energy conversion, and it can be harvested annually for a number of years without replanting.

1.4 Traditional Breeding: Breeding Objectives, Tools and Strategies, and Achievements

The objectives of sugarcane breeding programs around the world are to produce cultivars with improved characteristics such as increased cane yield, higher sucrose content, pest and disease resistance, tolerance to abiotic stress, and improved ratooning ability. Focused breeding programs have led to significant contributions to characters such as those listed above (Hogarth, 1976; Nuss, 2001).

Crossing of two parents is the first step in producing and selecting a new cultivar. If pollen and seed production do not occur naturally, as is the case in sugarcane growing areas with latitudes above 15° north and south, crossing is conducted in photoperiod glasshouse facilities where day length and temperature can be manipulated (Brett, 1974). Extensive evaluation of the progeny from the crosses is undertaken. The selection process

consists of several different stages and usually takes 10–14 years to release a variety. This prolonged period before a new sugarcane variety can be commercially released is largely due to the reliance of the selection process on phenotypic characters. At each stage, clones with unsuitable characters are discarded and the performances of selected clones are evaluated in larger plots (Parfitt, 2005).

Due to the narrow genetic base of modern varieties (Hogarth, 1987), sugarcane breeders have tried to exploit the genetic variation within the *Saccharum* complex, which shows great variation for a range of traits of interest to the breeders, such as sugar content, tolerance to drought and cold, pest and disease resistance, uprightiness, fiber content, tiller number, stalk size and strength, low suckering, easiness to detrash (suitability for mechanical, green harvest), and ratooning ability. Breeders have used *S. spontaneum*, *Miscanthus sinensis*, *Erianthus arundinaceus*, and *Erianthus rockii* in introgression initiatives.

S. spontaneum. In the development of modern sugarcane cultivars, an average of only 15–25% of chromatin is derived from *S. spontaneum* (D'Hont *et al.*, 1995), due primarily to the limited number of *S. spontaneum* genotypes used (Berding and Roach, 1987). Only two genotypes of *S. spontaneum* were used in the initial crosses made in the late 19th and early 20th centuries in India and Java (Martin, 1996). *S. spontaneum* has been considered as a source of positive alleles for traits involved in adaptation to different climatic conditions and for disease and insect resistance. Dunkelman and Breaux (1972) studied the agronomic habits of 32 apparently mosaic-resistant *S. spontaneum* genotypes to ascertain their potential utilization as breeding material, and found a genotype (US 56-15-8) particularly sweet, with a juice Brix reading of 11.5%. The characterization of sugar composition of *S. spontaneum* genotypes from the World Collection of *Saccharum* (Miami, Florida) also indicated that this species is a potential source of positive alleles for sugar content (Tai and Miller, 2001). These results were confirmed by da Silva *et al.* (2007) in a study involving molecular markers to test if alleles with positive effects for sucrose content could be found in *S. spontaneum*. Expressed sequence tags (ESTs) involved in sucrose accumulation from the metabolism of complex carbohydrate pathway (da Silva *et al.*, 2007) were

used to develop molecular markers. By targeting four functionally characterized sugar metabolism candidate genes to a set of 50 *S. spontaneum* genotypes showing variation in sugar content, *S. spontaneum*-specific polymorphic markers were identified. These markers are not present in commercial sugarcane genotypes and may therefore be used for tagging positive *S. spontaneum* alleles for introgression into commercial sugarcane genotypes. Efforts to introgress these alleles were made in 2005 at the US Department of Agriculture (USDA) Sugarcane Unit in Houma, Louisiana, with a cross involving the commercial cultivar HoCP00-950 and the *S. spontaneum* genotype MPTH97-216, from Thailand.

M. sinensis. A difficulty in breeding sugarcane for stress tolerance is the trade-off between stress tolerance and yield (Ming *et al.*, 2006). Developing varieties adapted to a wider range of climatic regimes could improve sugarcane production in water-restricted and/or colder regions. Sugarcane with increased water use efficiency and tolerance to drought or cold temperatures are critical selection criteria for that goal. Another way to overcome this difficulty would be to identify alternative alleles contributing to stress tolerance in the *Saccharum* complex and introgress these into commercial germplasm. Even though the water use efficiency of sugarcane is high, substantial amounts of water are required to maintain maximal growth and productivity. Since irrigation of sugarcane fields is limited, and irrigation of biomass crops is unlikely to be economic, it is important to identify genotypes that are tolerant to water stress. Screening with Paraquat (methyl viologen) for drought tolerance in sugarcane (Ming *et al.*, 2001b), wheat, and barley (Altinkut *et al.*, 2001) has proved to be a rapid and practical screening method, in conjunction with chlorophyll fluorescence measurements, for identifying and characterizing genetic variation in sugarcane water stress tolerance (Ming *et al.*, 2006).

Miscanthus species are exceptionally tolerant to low temperature and drought and are among the few plants in temperate climates that use the C4 photosynthetic pathway (Naidu *et al.*, 2003). In a study comparing drought tolerance of different *Miscanthus* species (*M. sacchariflorus*, *M. giganteus*, and *M. sinensis*), *M. sinensis* was the only one that did not show senescence caused by water deficit (Clifton-Brown *et al.*, 2002).

M. sinensis retained all of its green expanded leaf area irrespective of water supply, showing its complete resistance to senescence. Similarly, when commercial varieties, breeding lines and seedlings of sugarcane and *Miscanthus* were exposed to freezing temperatures for at least 2 h in the Rio Grande Valley of Texas in 2004, leaf damage was observed on all sugarcane plants, but not on *Miscanthus* × *Saccharum* sp. hybrid seedlings (Figure 1). *Miscanthus* species also have high cellulose fiber content and are considered a potential energy crop by the European Union (EU) (Clifton-Brown *et al.*, 2004).

If the superior drought and cold tolerance and high fiber of *Miscanthus* could be combined with the photosynthetic capacity of commercial sugarcane, it would be possible to produce a low-input, high-biomass, drought- and cold-tolerant energy crop. As *M. sinensis* ($2n = 2x = 38$) is closely related to sugarcane, it produces viable hybrids when crossed with sugarcane (Grassl, 1967; Lo *et al.*, 1986), and can be seen as a source of stress

tolerance genes for introgression purposes. Atienza *et al.* (2003) have shown that it is feasible to develop a marker-assisted selection program for biomass production in *Miscanthus* using quantitative trait loci (QTL) to detect markers for traits such as diameter, height, and panicle size. These QTLs could assist in introgression work.

Erianthus species. The *Erianthus* genus contains eight species (Aitken *et al.*, 2007) and is also a potential donor for stress-resistant genes. *E. arundinaceus* has several traits desirable to sugarcane breeders such as tolerance to drought and waterlogging, high resistance to *Pachymetra* root rot, vigor, and good ratooning performance (Berding and Roach, 1987). Many attempts have been made to generate sugarcane × *E. arundinaceus* hybrids. *In situ* hybridization analysis of progeny from some of these crosses indicated that the introgressions were successful (D'Hont *et al.*, 1995; Figure 2). However, only one appears to have been successful in producing fertile offspring. Cai *et al.* (2005) describe the

Figure 1 *Miscanthus sinensis* × *Saccharum* sp. hybrid seedlings showing cold tolerance under subfreezing field conditions

Figure 2 Chromosomes from a root-tip cell of an intergeneric hybrid fluorescing after genomic *in situ* hybridization. *Saccharum officinarum* chromosomes are green and *Erianthus arundinaceus* chromosomes are red [Reproduced with permission from George Piperidis, BSES Limited]

intergeneric hybridization of two populations using the *S. officinarum* Badilla as the female parent in both crosses with pollen from three different *E. arundinaceus* clones from Hainan, China. They also describe the backcrossing of the F₁ hybrid, YC96-40 with sugarcane cultivar CP84-1198 to generate the backcross 1 (BC₁) population, demonstrating the fertility of the intergeneric hybrid. Molecular markers were used to confirm both the introgression into the F₁ and BC₁ populations and the parentage of the BC₁s.

E. rockii. A species originating in the Yunnan, Sichuan, and the Tibetan regions of China, has good vigor, cold and drought tolerance, and good ratooning ability. *E. rockii* was recently reported by Aitken *et al.* (2007) to have been successfully used as the male parent for intergeneric hybridization with (1) Vietnam-niuzhe (*S. officinarum*) and (2) interspecific hybrid Fiji (*S. officinarum* × *S. spontaneum*). Using amplified fragment length

polymorphisms (AFLP), Aitken *et al.* (2007) showed that all of 10 screened *E. rockii* × *S. officinarum* crosses were true intergeneric hybrids, but that 9 of 10 of the *E. rockii* × Fiji crosses were selves of the *E. rockii* female parent and only one was a true introgression. Further analysis showed that there was a ($n + n$) transmission of gametes.

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Approaches

Conventional breeding in sugarcane has several limitations that can be overcome by transgenic approaches. Listed below are a few such examples.

1. Commercial sugarcane cultivars possess different proportions of chromosomes, complex recombinational events, and varying chromosome sets (aneuploidy) (Sreenivasan

et al., 1987). This genomic complexity brings difficulties in applying conventional plant breeding for cultivar improvement. In addition, conventional breeding is a multistage, laborious, and time-consuming process requiring 10–14 years to develop a new cultivar. A single fault, such as disease susceptibility in an otherwise elite cultivar, could cause the cultivar to be abandoned. Conventional breeding approaches to correct such faults in an existing cultivar are impractical in sugarcane, due to the genetic complexity of cultivars (Birch and Maretzki, 1993). The capacity to introduce specific genes by transgenic approach, without major genetic reassortment following crossing, could be used to rescue flawed cultivars (Birch and Maretzki, 1993). For example, the successful production of sugarcane plants resistant to leaf scald disease was achieved by transgenic approach (Zhang *et al.*, 1999).

2. Although breeding efforts in sugarcane have been successful in increasing cane production, only limited success has been achieved recently in increasing sugar content. For example, there has been no increase in sugar content over the last 40 years in Australian sugarcane (Bonnett *et al.*, 2004b). In the USA, Legendre (1995) reported that the average sucrose content of new candidate varieties decreased 3.5% on the fifth cycle of recurrent selection, as compared to the previous cycle, indicating that a limit has been reached for this trait. The QTL analysis of interspecific F₁ populations also indicated that modern sugarcane cultivars have a limited (biased subset) population of genes controlling sugar content (Ming *et al.*, 2001b). In contrast, metabolic engineering of sugarcane through transgenic approaches could improve sugar content. For example, transgenic sugarcane with doubled sugar content was achieved when attempting to produce isomaltulose in sugarcane (Wu and Birch, 2007).
3. Production of novel products in sugarcane is not possible by conventional breeding. In contrast, metabolic engineering through transgenic approaches could produce new products, such as alternative sugars, biopolymers, pharmaceuticals, and high-value proteins. For example, successful production of sorbitol (Chong *et al.*, 2007), isomaltulose (Wu and

Birch, 2007), *p*-hydroxybenzoic acid (pHBA) and biodegradable polymer (McQualter *et al.*, 2005; Petrasovits *et al.*, 2007) has been achieved in transgenic sugarcane, which cannot be achieved through conventional breeding.

4. Conventional breeding allows transfer of traits and genes only between sexually compatible species. Hence, transfer of traits from noncompatible species is impossible. In contrast, transgenic approaches allow insertion of novel genes from sexually noncompatible plants/organisms, enable expression of native genes at different levels in specific tissues or under novel developmental patterns of expression.
5. The number of traits to be considered when selecting for variety development is determined by the degree of genetic linkage among those traits. If linkages are rare, several traits can be selected simultaneously. In the case of sugarcane the extent of those linkages is still uncertain (Ming *et al.*, 2006). Recent advances in molecular marker-assisted selection and transformation technologies can alleviate the problem. Thus, genetic transformation by modern molecular techniques (see in Section 2) has the potential to enhance a host of traits including sugar, pest and disease resistance, tolerance to drought and cold, vigor, plant architecture and fiber, and to produce alternative products such as biopolymers and isomaltulose in sugarcane.

2. DEVELOPMENT OF TRANSGENIC SUGARCANE

Sugarcane is a prime candidate for the application of genetic engineering, as single characters can be introduced into the complex genetic background of elite commercial clones to correct negative factors, such as disease susceptibility. Successful genetic engineering requires a reliable tissue culture system and efficient transformation methods. Sugarcane was one of the first monocotyledonous crop plants used successfully for establishment of tissue cultures (Barba and Nickell, 1969; Nickell and Maretzki, 1969), regeneration of plants (Heinz and Mee, 1969), and isolation of protoplasts (Maretzki and Nickell, 1973; Nickell and Heinz, 1973).

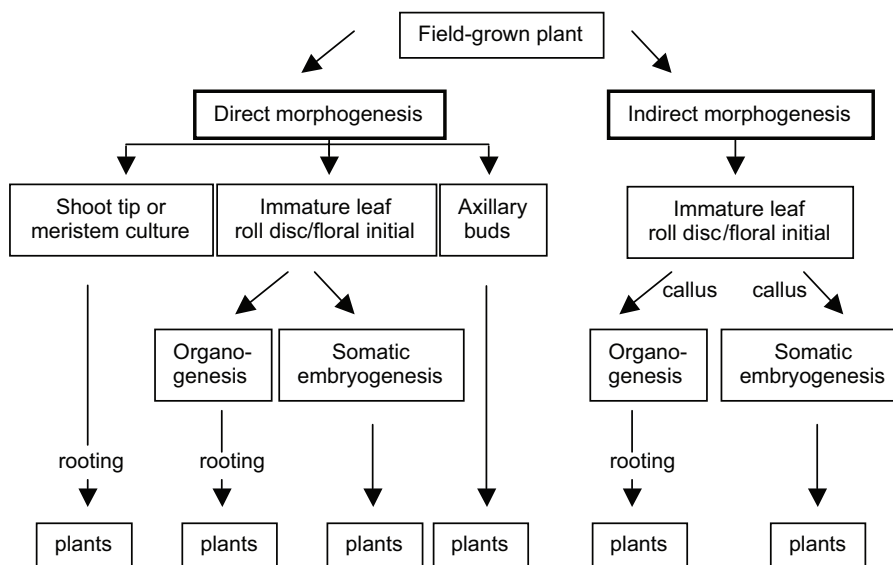

Figure 3 Summary of direct and indirect morphogenic pathways for sugarcane regeneration. In the routes where the rooting event is noted, external application of growth hormones is usually required for root production

2.1 Tissue Culture and Transformation

The early-established robust tissue culture/regeneration system of sugarcane became a foundation for efficient genetic transformation of this crop. The explant most frequently used for transformation experiments in sugarcane is embryogenic callus. This callus is produced from the culture of immature leaf whorls immediately above the apical meristem. The whorls are sliced into thin (2–3 mm) transverse sections and cultured on Murashige and Skoog (MS) medium (Murashige and Skoog, 1962) supplemented with an auxin (usually 2,4-dichlorophenoxyacetic acid) and sucrose, and subcultured every 3–4 weeks. Prolific compact embryogenic callus is produced within 2 months. However, this varies with different clones and needs to be optimized for the genotype being used.

2.1.1 Regeneration of plants

Sugarcane has a well-established history of *in vitro* regeneration that began in the late 1960s (Heinz and Mee, 1969). Regeneration of sugarcane can occur via several different pathways (Figure 3) (reviewed by Snyman, 2004; Laksh-

manan, 2006; Lakshmanan *et al.*, 2005). The pathways of regeneration by somatic embryogenesis or organogenesis have been well characterized and documented (Ho and Vasil, 1983; Guiderdoni and Demarly, 1988; Taylor *et al.*, 1992). For the regeneration of transgenic plants *in vitro*, the route of morphogenesis is dependent on the explant targeted for DNA delivery. Criteria for explant choice are: (i) a large number of regenerable cells and (ii) maintenance of regenerative capacity during the selection procedure.

Where embryogenic callus is used as the recipient material for foreign DNA, regeneration is via somatic embryogenesis (Bower *et al.*, 1996; Falco *et al.*, 2000) or organogenesis (Gallo-Meagher and Irvine, 1996). Although transgenic plants have been successfully generated via indirect morphogenesis, limitations include the amount of time taken to regenerate a transgenic plant (36 weeks from DNA delivery to glasshouse transfer) (Bower *et al.*, 1996; Snyman *et al.*, 2000) and the incidence of somaclonal variation as evidenced in agronomic variability when plants are evaluated in the field (Grof and Campbell, 2001; Vickers *et al.*, 2005b).

Alternative tissue targets for transgene delivery have been sought, such as exposed apical meristems from axillary buds followed by shoot

morphogenesis (Gambley *et al.*, 1993, 1994; Manickavasagam *et al.*, 2004), leaf roll discs (Snyman *et al.*, 2000, 2001) and pre-emergent inflorescences (Snyman *et al.*, 2006) followed by direct somatic embryogenesis. Although these methods have resulted in transformed plants in a reduced time frame compared to protocols employing indirect embryogenesis, determination of phenotypic fidelity in the field has yet to be published.

2.1.2 Transformation methods

Initial work on sugarcane transformation targeted protoplasts as recipient cells and DNA delivery was via polyethylene glycol (PEG) (Chen *et al.*, 1987) or electroporation (Rathus and Birch, 1992). However, neither technique resulted in the production of transgenic plants, as sugarcane regeneration from protoplasts is notoriously difficult. A significant milestone in sugarcane transformation was achieved when particle bombardment of embryogenic callus was reported and a protocol for recovery of transgenic plants was described (Bower and Birch, 1992). Embryogenic callus proved to be a reliable source of tissue for further refinement of microprojectile bombardment protocols and for the production of transgenic plants in several parts of the world (Bower *et al.*, 1996; Gallo-Meagher and Irvine, 1996; Snyman *et al.*, 1996; Joyce *et al.*, 1998; Ingelbrecht *et al.*, 1999; Falco *et al.*, 2000). In addition, *Agrobacterium*-mediated DNA delivery was also developed using embryogenic callus as recipient cells (Arencibia *et al.*, 1998; Elliott *et al.*, 1998; Enriquez-Obregon *et al.*, 1998; Liu *et al.*, 2003).

Microprojectile bombardment using a gene gun has been achieved using either the particle inflow gun (PIG) (Finer *et al.*, 1992) or a BioRad device (Heiser, 1993). The principle of this transformation method is to coat either tungsten or gold particles with plasmid DNA containing the gene(s) of interest and to bombard these particles into embryogenic sugarcane callus using pressurized helium combined with a partial vacuum chamber. The first report of successful transformation of sugarcane suspension culture cells using the PIG gun was by Birch and Franks (1991) using the *GUS* (β -glucuronidase) reporter gene and kanamycin selectable marker gene, although no plants were

regenerated. This approach was further refined by Bower and Birch (1992) and is now widely adopted for the production of transgenic sugarcane (Bower *et al.*, 1996; Gallo-Meagher and Irvine, 1993, 1996; Franks and Birch, 1992; Snyman *et al.*, 1996; Joyce *et al.*, 1998; Ingelbrecht *et al.*, 1999; Falco *et al.*, 2000). Transformation efficiencies vary depending on genotype, quality of embryogenic callus, length of time spent *in vitro*, and selection regime employed, but most laboratories have developed a protocol that suits their requirements.

The desire to minimize transgene copy number and integration complexity, coupled with advances reported in *Agrobacterium*-mediated transformation in other monocotyledonous crops (reviews by Cheng *et al.*, 2004; Shrawat and Lorz, 2006; Wang and Ge, 2006), made this an appealing system to develop in sugarcane. Although not widely applied yet, *Agrobacterium*-mediated transformation using embryogenic callus and four different strains of *Agrobacterium* (Arencibia *et al.*, 1998; Elliott *et al.*, 1998; Enriquez-Obregon *et al.*, 1998; Liu *et al.*, 2003) and axillary buds with two strains (Manickavasagam *et al.*, 2004) has been reported. Although it is difficult to compare transformation efficiencies between the above papers, it appears that pretreatment of the callus prior to *Agrobacterium* co-cultivation improves transformation efficiency (e.g., a 30 min dehydration period). In addition, selection of a particular size of callus (1000 μm) (Arencibia *et al.*, 1998), and use of antinecrotic compounds (2 mg l^{-1} silver nitrate; 15 mg l^{-1} ascorbic acid (Enriquez-Obregon *et al.*, 1998) were reported to be advantageous. In both papers, Arencibia *et al.* (1998) and Enriquez-Obregon *et al.* (1998), the transgene copy number was 1–3. Elliott *et al.* (1998) applied no selection pressure for up to 6 weeks after co-cultivation. After this period, GFP (green fluorescent protein)-positive calli were visually selected and transferred to bialaphos at 1 mg l^{-1} . Two transgenic plants were regenerated that contained three and seven copies of the *GFP* gene, respectively.

More recently, transgenic plants were generated using axillary meristems of sugarcane (Manickavasagam *et al.*, 2004). This novel approach resulted in a transformation efficiency of 49.6%. They used two strains of *Agrobacterium*, LBA4404 and EHA105. The plasmid pGA492 contained the *nptII* (neomycin phosphotransferase) gene

driven by the *nos* (nopaline synthase) promoter and the *bar* and *gus* genes driven by cauliflower mosaic virus (CaMV) 35S promoter. Selection was on 5 mg l⁻¹ bialaphos, applied immediately after the co-cultivation period. Transformation efficiency was greatest in both strains when co-cultivation period was for 3 days in the presence of 50 µM acetosyringone. Thousands of plants were produced within 5 months. Although chimeric plants were reported, the incidence was eliminated in secondary shoots after five rounds of selection on Basta[®]-containing medium. When these plants were transferred to the greenhouse and sprayed with herbicide, a total of 336 plants (clones of 10 independent transformation events) representing 50% of total plants screened, displayed herbicide resistance. Southern blot analysis on a small subset of these plants further confirmed the presence of 1–2 copies of the transgene in each plant.

2.1.3 Selection of transformed tissues

Studies on transgenic sugarcane for technology development have involved marker and reporter genes. The reporter genes used include *GUS* (Jefferson *et al.*, 1987; Gnanasambandam and Birch, 2004; Braithwaite *et al.*, 2004), luciferase (*luc*) (Mudge *et al.*, 1996b; Gnanasambandam and Birch, 2004), maize anthocyanin regulatory elements (R and C1) (*ANT*) (Ludwig *et al.*, 1990; Bower *et al.*, 1996; Gnanasambandam and Birch, 2004), and *GFP* (Elliott *et al.*, 1998; Gnanasambandam and Birch, 2004; Gnanasambandam *et al.*, 2007; Petrasovits *et al.*, 2007). Comparative studies by Bower *et al.* (1996) on the suitability of *GUS*, *luc*, and *ANT* as reporter genes for transient assays in sugarcane transformation indicated that

the *ANT* system is the most suitable reporter system. *ANT* expression is visible within 8 h after bombardment and steadily increases in intensity up to 48 h after bombardment. The expressing cells remained visible in the target tissue for 2–3 weeks, before fading or being overgrown. In addition, the results were not confounded by background *ANT* activity. In contrast, the main disadvantage of using the *GUS* reporter gene is that the conditions for detection of gene activity are lethal to plant cells and therefore the transformed event is subsequently lost. Detection of both *luc* and *GFP* genes require specialized camera and/or detection systems. In addition, GFP detection is confounded by autofluorescence of the callus and chlorophyll in green plant tissues. However, the power of confocal laser scanning microscopy allows precise visualization of fluorescent signals within a narrow plane of focus, and the reconstruction of three-dimensional structures from serial optical sections (Haseloff *et al.*, 1997). This is an advantage of GFP over both GUS and *luc* (Gnanasambandam and Birch, 2004).

The most widely adopted stable-integration antibiotic marker used for sugarcane transformation is the *aphA2* *Escherichia coli* Tn5-derived *nptII*. The first successful application of the *nptII*-based selection system was reported as a step-wise incremental procedure using geneticin (Bower and Birch, 1992). This formed the foundation for subsequent protocols utilizing geneticin (also known as G418) (Bower *et al.*, 1996; Falco *et al.*, 2000; Snyman, 2004) or paromomycin (Joyce *et al.*, 2006a) as the selective agent (Table 1). Less widely used is the hygromycin phosphotransferase (*hph*) gene with selection on 20 mg l⁻¹ hygromycin (Arencibia *et al.*, 1998; Carmona *et al.*, 2005).

The first paper reporting herbicide resistance in sugarcane also described a selection procedure

Table 1 Selectable marker genes used in sugarcane transformation

incorporating a herbicidal agent, bialaphos (Gallo-Meagher and Irvine, 1996). The *bar* and *pat* genes from *Streptomyces hygroscopicus* and *Streptomyces viridochromogenes*, respectively, encode the phosphinothricin acetyltransferase enzyme that leads to detoxification of phosphinothricin and its derivatives that are ingredients in some commercial herbicides. Selection using herbicides has been used widely, although each laboratory has to determine empirical regimes for selection of different explants and genotypes and formulations of active ingredients differ (Gallo-Meagher and Irvine, 1996; Enriquez-Obregon *et al.*, 1998; Manickavasagam *et al.*, 2004) (Table 1).

The use of the above genes, in addition to selection of transformed cells and plants, has been beneficial in generating information about transgene expression and stability in transgenic sugarcane (Gallo-Meagher and Irvine, 1996; Enriquez-Obregon *et al.*, 1998; Leibbrandt and Snyman, 2003).

There is limited published work on the use of positive selection systems, such as the *E. coli manA* phosphomannose isomerase (PMI) gene, in sugarcane. The ubiquitous plant enzyme hexokinase converts mannose to mannose-6-phosphate (Man-6-P). Man-6-P is toxic to plants, but most plants lack PMI and are inhibited by the accumulation of Man-6-P. PMI catalyzes the reversible interconversion of Man-6-P and fructose-6-phosphate, thereby releasing the Man-6-P inhibition and making mannose available as a carbon source for the plant. This system was first demonstrated for transformation of potato, sugar beet, and maize (Bojsen *et al.*, 1998, 1999) and since then it has been used successfully in a variety of other plant species. PMI has no adverse effects in acute mouse oral-toxicity tests, generates no detectable biochemical changes in mannose-associated pathways (Privalle *et al.*, 1999), lacks many attributes known to be associated with allergens (Privalle, 2002), and may thus be considered as an ideal selection protein for plant transformation. For sugarcane transformation, calli were selected on media containing 3 g l^{-1} mannose, in addition to the 20 g l^{-1} sucrose present in the media (Jain *et al.*, 2006). Plant regeneration was performed under the same level of selection. An increase of mannose from 1.5 to 3 g l^{-1} for rooting improved the overall transformation efficiency. The PMI encoding gene,

manA, was stably integrated and expressed in almost all of the transgenic lines.

Of the other nonantibiotic systems tested in sugarcane, glutamate-1-semialdehyde aminotransferase was unsuitable, while selection incorporating arabinol showed up to 100-fold lower transformation efficiency. In addition, arabinol is expensive, making it a less desirable selection agent.

2.1.4 Promoters and termination sequences

The two main sources for promoters are from microorganisms (viral or bacterial) or from plants. In addition, there are a few synthetic promoters that have been constructed in the laboratory by combining regulatory and/or enhancer elements from different viral or plant promoters. What is lacking in sugarcane, and in monocots in general, is a promoter that functions as strongly as the CaMV 35S promoter does in dicots. Schledzewski and Mendel (1994) compared transient reporter gene expression in transgenic cells of barley, maize, and tobacco driven by maize polyubiquitin1 (*Ubi-1*), rice *actin1*, *Emu*, or CaMV 35S promoter. CaMV 35S promoter had the highest GUS activity in tobacco ($316.71 \text{ nmol h}^{-1}$) compared to maize (9.88 nmol h^{-1}) and barley (1.22 nmol h^{-1}). In contrast, of the four promoters tested, the *Ubi-1* promoter showed highest expression in both maize and barley cells, but not in tobacco. However, CaMV 35S in tobacco showed a promoter strength equivalent to 2.5- to 5-fold greater than *Ubi-1* in maize (Table 2).

2.1.4.1 Viral promoters

The viral promoter most frequently used in plant transformation is the CaMV 35S promoter. However, this promoter is not highly expressed in sugarcane (Table 2). Schenk *et al.* (2001) reported the isolation of two novel promoters from a DNA virus that infects banana (banana streak virus, BSV). The region of two BSV isolates (2105 bp and 1322 bp) upstream of the open reading frame (ORF) were labeled as Mys and Cav, respectively, and assessed for promoter activity in stably transformed sugarcane callus using GFP (*sGFPs65T*) as a reporter gene.

Table 2 Reporter gene expression analysis in sugarcane

Results of the promoter analysis showed that after 19 months growth, the plants transformed with the BSV-Cav construct showed greater than threefold higher activities than the maize *Ubi-1* promoter ($10.62 \mu\text{g GFP mg}^{-1}$ total protein and $3.2 \mu\text{g GFP mg}^{-1}$ total protein, respectively). In addition, this promoter appeared to be expressing in a constitutive manner. GFP accumulation was observed in vascular tissue, bundle sheath cells as well as leaf parenchyma and epidermal cells of sugarcane. Expression, however, was strongest in the parenchyma cells with all three promoters.

Promoters from a sugarcane-specific badnavirus (sugarcane bacilliform virus, SCBV) were cloned and tested using two marker genes (*GUS* or *nptII*) (Braithwaite *et al.*, 2004). Three of the four promoters tested were amplified by polymerase chain reaction (PCR) from sugarcane plants containing the virus while the fourth promoter was subcloned from an almost genome-length clone of SCBV. All four promoters were active in sugarcane, with the highest GUS expression present when the subcloned region of SCBV was used for promoter construction. When different parts of the plantlets were assessed for GUS expression (Table 2), the meristems of young plants had the highest levels, there was some in young leaves, but no expression in roots. When *nptII* expression was assessed in young *in vitro* plantlets, however, transgene activity was present in callus, leaves, and roots to a similar level ($<0.01\%$ of total soluble protein). Thus, the lack of GUS activity in the roots may be a consequence of poor penetration of the GUS substrates to the root region. Interestingly, when the *nptII* transgenics were grown to maturity in the glasshouse, the lines driven by the SCBV promoter showed a five-fold higher activity than the *Ubi-1*-driven plants (Table 2).

2.1.4.2 Plant-derived promoters

The maize *Ubi-1* promoter (Christensen and Quail, 1996) is the most frequently used constitutive promoter for sugarcane transformation (Table 2) and its expression is usually higher than other plant-derived promoters (sugarcane *Ubi* and rice *actin1*). Expression of *luc* activity in sugarcane plants by maize *Ubi-1* promoter ranged between 200 and 300 000 relative light units (RLU) mg^{-1} protein compared to 200–2000 RLU mg^{-1} protein

in *actin1* lines (Hansom *et al.*, 1999; Table 2). In addition, this expression was independent of copy numbers.

Using particle bombardment of sugarcane callus, Liu *et al.* (2003) showed that there was a 1.6-fold increase in GUS expression by the rice *Ubi-2* promoter (mean = $78.6 \text{ nmol 4-MU min}^{-1} \text{ mg}^{-1}$ protein) over the maize *Ubi-1* promoter (mean = $47.6 \text{ nmol 4-MU min}^{-1} \text{ mg}^{-1}$ protein). The *GUS* gene driven by CaMV 35S showed no expression in regenerated plants, and was $<10\%$ of that of ubiquitin promoters in transient expression analysis (Table 2).

Tang *et al.* (1996) compared the expression patterns of GUS, driven by promoters of two sugarcane ribulose-1,5-bisphosphate small subunit (Rubisco) genes (*scrbc-1* and *-2*), in transient assays. Both promoters directed expression in leaf tissues, but not in calli. Although the overall expression levels were lower when compared to the maize *Ubi-1* promoter, *scrbc* promoters drove higher expression in the photosynthetic cells, especially in the bundle sheath cells (Table 2). Stable expression in transgenic callus lines and regenerated plants also showed that *scrbc-1* promoter directed GUS expression in leaves, but not in calli.

Two sugarcane polyubiquitin gene promoters (sugarcane *ubi4* and *ubi9*) were found to direct high levels of transient GUS expression in the following monocots: sugarcane, maize, sorghum, banana, pineapple, garlic, and rice cells (Wei *et al.*, 1999, 2003). Both of these monocot promoters were also sufficient to drive GUS expression in cells of tobacco. In these transient assays, the activities of the two sugarcane promoters were comparable to the strong monocot promoter, maize *Ubi-1* (Christensen and Quail, 1996). Similar to *Ubi-1*, sugarcane *ubi4* was heat shock inducible in stably transformed sugarcane callus lines, but sugarcane *ubi9* was not (Wei *et al.*, 2003). The physiological difference between the two sugarcane ubiquitin promoters corresponded to a MITE (miniature inverted-repeat transposable element) insertion that is present in the putative heat shock elements of sugarcane *ubi9* but not present in sugarcane *ubi4*. In transgenic sugarcane plants produced by particle gun bombardment, GUS expression from sugarcane *ubi4* and *ubi9* dropped to very low or nondetectable levels after plant regeneration. This drop in expression also occurred in *Ubi-1*

sugarcane lines. Nuclear run-on experiments showed the down-regulated transgenes continued to be transcribed at high levels, indicating that the lack of transgene expression was due to post-transcriptional gene silencing (PTGS). In contrast, sugarcane *ubi9* drove high levels of expression in transgenic rice plants produced via *Agrobacterium*-mediated transformation. This high level of expression continued after plant regeneration and was inherited in the T₁ generation (Wei *et al.*, 2003).

2.1.4.3 Synthetic promoters

The promoter *Emu* was synthesized by Last *et al.* (1991) and contains a truncated maize alcohol dehydrogenase (*Adh*) promoter as well as several copies of the maize anaerobic responsive elements from the *Adh* gene. In addition, it contains the *ocs*-element of the octopine synthase gene from *Agrobacterium*. Comparative studies of GUS expression in sugarcane protoplasts using constructs with either the *Emu* or the CaMV 35S promoter showed a 50–100-fold increase in *Emu*-driven GUS expression over the 35S promoter (Rathus and Birch, 1992). However, Joyce *et al.* (1998) and Bower *et al.* (1996) found that the *Emu* promoter could not drive strong expression in mature sugarcane plants (Table 2).

Osa is another synthetic promoter, developed by CSIRO Plant Industry Australia, which consists of multiple octopine synthase (OCS) enhancer elements, the core region from the CaMV 35S promoter and untranslated leader sequence from maize transposable element *Ac* (Bower *et al.*, 1996). Experiments in sugarcane using this promoter also showed much lower levels of gene expression than maize *Ubi-1* (Table 2).

2.1.4.4 Terminator sequences

The most commonly used terminator sequences for transformation of sugarcane callus is the *Nos* terminator sequence from *Agrobacterium*. There are a few reports where the *Agrobacterium* octopine synthase gene (*Ocs*) terminator sequence has been used (Elliott *et al.*, 1998). The studies have not compared the effect of terminator sequences on transgene expression in sugarcane; this is an

area of research that has been neglected and warrants further investigation.

2.1.5 Activity, stability of inheritance, and silencing of transgenes

The high level of ploidy found in all sugarcane may have some important implications for transformation, which are not normally encountered when working with diploid species. For instance, increase in ploidy by genome duplication, which has been suggested to play an important role in angiosperm evolution (Stephens, 1951; Ohno, 1970; Blanc *et al.*, 2000; Initiative, the Arabidopsis Genome, 2000; Paterson *et al.*, 2000, 2003, 2004, 2005; Bowers *et al.*, 2003; Vandepoele *et al.*, 2003; Wang *et al.*, 2005b), is associated with a host of rapid responses, including loss and restructuring of low-copy DNA sequences (Song *et al.*, 1995; Feldman *et al.*, 1997; Ozkan *et al.*, 2001; Shaked *et al.*, 2001; Kashkush *et al.*, 2002), activation of genes and retrotransposons (O'Neill *et al.*, 1998; Kashkush *et al.*, 2003), gene silencing (Chen and Pikaard, 1997a, b; Comai, 2000; Comai *et al.*, 2000; Lee and Chen, 2001), and organ-specific subfunctionalization of gene expression patterns (Adams *et al.*, 2003, 2004). Sugarcane appears to have undergone two such genome duplications in about the past 5 million years and these mechanisms may be especially important in providing raw material for evolutionary change. It is important to understand how stable the sugarcane genome is with respect to: (i) transposon activity; (ii) genome expansion or contraction; (iii) measuring the extent of gene silencing and alterations in gene expression; (iv) assessing *in vitro* regeneration systems for epigenetic variation in regenerated plantlets; and (v) designing transformation technologies to overcome the above constraints.

Molecular techniques for detection and characterization of transgenes with respect to integration pattern, copy number, and protein concentrations have been conducted and published (Bower *et al.*, 1996; Gallo-Meagher and Irvine, 1996). However, these analyses were carried out on sugarcane plants maintained in glasshouses. Field analysis to determine expression and stability of transgenes is important because of sugarcane's multiple vegetative crop cycles and reports of PTGS.

The transgenesis approach in sugarcane has targeted elite commercial cultivars. It would be advantageous to be able to use transgenic plants as parents in breeding programs especially when the desired trait is not present in the sugarcane gene pool. Transgene inheritance and segregation of the *bar* herbicide resistance gene and the *hut* Sorghum mosaic virus (SrMV) coat protein gene was tracked in progeny arising from conventional crosses made between transgenic and nontransgenic parents (Butterfield *et al.*, 2002). The results demonstrated that transgenic plants can be used as parents in a sugarcane breeding program but screening progeny for a characteristic such as virus resistance that relies on PTGS mechanisms may have to be carried out after one vegetative cycle of growth after crossing.

PTGS is known to occur in sugarcane (Ingelbrecht *et al.*, 1999) and is considered to be one of the factors limiting accumulation of recombinant proteins (Wei *et al.*, 2003). It was thought that it could be reversed by retransformation with a gene encoding a viral suppressor of PTGS, such as HcPro from SrMV (Ingelbrecht *et al.*, 2000) and P0 from sugarcane yellow leaf virus (ScYLV) (Wang *et al.*, 2006, 2007). Despite the potential application in transgene silencing control, there are possible negative effects on endogenous gene regulation and virus susceptibility. Initial results indicate that there is no consistent correlation between the RNA expression levels of P0 or HcPro and the expression of a transgene and several miRNA-regulated endogenous genes. Further research is required to characterize the effect of these viral suppressors in transgenic sugarcane (Wang *et al.*, 2006, 2007).

Sugarcane plants transformed via particle bombardment with GM-CSF (human cytokine granulocyte macrophage colony stimulating factor), contain numerous copies of transgenes with complex integration patterns as revealed by Southern blot hybridization (Albert *et al.*, 2003; Wang *et al.*, 2003). Multiple approaches have been evaluated for the introduction of single- or low-copy transgenes, to determine if these methods can reduce transgene silencing (Albert *et al.*, 2004). These methods include the use of insert-only DNA for bombardment (Fu *et al.*, 2000), Cre/*lox* site-specific recombination to resolve multiple transgene copies (Srivastava and Ow, 2001), and the *Ac/Ds* transposon system to direct

transgene integration by transposition (Koprek *et al.*, 2000, 2001). The use of linear expression cassette-only DNA was reported to produce a high frequency of low-copy transgene insertions in rice, with no evidence of silencing through the R₄ generation (Fu *et al.*, 2000). In contrast, most transgenic sugarcane lines produced by this method contained multiple transgene copies, with only three of 27 selected lines containing three or fewer copies (Wang *et al.*, 2003). Cre/*lox* lines did contain fewer copies of the transgene as estimated by quantitative PCR (qPCR). However, accumulation of GM-CSF in the low-copy lines was not higher than in multicopy lines (Albert *et al.*, 2004). In addition, a vector system was developed to allow direct plasmid to chromosome transposition using *Ac/Ds* in monocot cells. This should allow single-copy transposition lines to be produced in a single generation without sexual crosses (Albert *et al.*, 2003). However, no increase in GM-CSF protein level was observed in the *Ac/Ds* lines.

2.1.6 Adverse effects on growth, yield, and quality

Most evaluation of transgene stability and expression patterns and performance of transgenic sugarcane plants in the field has been limited to a few lines (Gallo-Meagher and Irvine, 1996; Arencibia *et al.*, 1999; Leibbrandt and Snyman, 2003). However, results of recent studies where a larger number of lines were tested (Gilbert *et al.*, 2005; Vickers *et al.*, 2005b) may influence future transgenic approaches.

Initial field trials demonstrated stable expression of a herbicide-resistant transgene over three rounds of vegetative propagation in a single transformant (Gallo-Meagher and Irvine, 1996; Leibbrandt and Snyman, 2003), but no agronomic measurements were taken in the first study. In the latter trial, no differences were found between the transgenic line and wild-type control in phenotypic characters such as stalk height and diameter, agronomic performance indicators such as sucrose yield and fiber content, and disease susceptibility ratings to smut and rust. However, in a field trial where 100 transgenic lines were compared for Sugarcane mosaic virus (SCMV) resistance and yield characteristics, a

considerable amount of variability for measured parameters was reported, which the authors attributed largely to the effects of the cultivar used and the tissue culture process (Gilbert *et al.*, 2005; Vickers *et al.*, 2005b). Similarly, preliminary data from metabolomic analysis, comparing leaves from nontransformed sugarcane with leaves from transgenic sugarcane lines producing polyhydroxybutyrate (PHB), found that the vast majority of the variation was a tissue culture effect and was not from the insertion of the PHB metabolic pathway and the selectable marker genes (Purnell *et al.*, 2007).

2.1.7 Subcellular targeting

Most transgene expression constructs used for sugarcane transformation result in production of foreign gene products in the cytosol, but important metabolic activities ranging from photosynthesis to sugar storage are carried out in other compartments. Hence, targeting proteins to subcellular compartments may be necessary for effective resistance to pest and diseases and efficient metabolic engineering in sugarcane. For example, for increased resistance to sugarcane leaf-scald disease, resistance gene products may need to be targeted to the plastids, as the albicidin toxin from the pathogen *Xanthomonas albilineans* blocks plastid DNA replication and chloroplast development. Similarly, for efficient conversion of sucrose to alternative carbohydrates such as starch and fructans, foreign proteins need to be targeted to the sugarcane vacuoles in mature stem parenchyma cells, where most of the sucrose is stored.

The ability to target recombinant proteins to the correct subcellular location using efficient and appropriate targeting signals is one of the most important requirements for sugarcane metabolic engineering. Various targeting signals have been successfully tested to target heterologous proteins to different subcellular compartments in sugarcane. The availability of visible reporters such as GFP in combination with a transient assay system in sugarcane leaves allowed the testing of the efficiency of various targeting signals with less time and resources (Gnanasambandam *et al.*, 2007). While most of the tested signal sequences are from dicotyledons species, they were effective

in the monocotyledon sugarcane. So far, targeting signals for vacuoles, endoplasmic reticulum (ER), plastids, mitochondria, and peroxisomes have been tested in sugarcane (McQualter *et al.*, 2005; Petrasovits *et al.*, 2007; Brumbley *et al.*, 2006b; Gnanasambandam *et al.*, 2007). In future, signals for other compartments and efficiency of signals will be determined.

2.1.7.1 Protein targeting to vacuoles

Sugar storage vacuoles occupy about 80% of the total tissue space in mature sugarcane stem and accumulate sucrose up to 500 $\mu\text{mol g}^{-1}$ fresh weight (Moore, 1995). Due to the potential to engineer synthesis of valuable compounds other than sucrose in sugarcane (e.g., alternative carbohydrates such as starch and fructans), the sugarcane vacuole is one of the important target compartments for metabolic engineering. However, targeting proteins to the sugarcane vacuoles remains a challenge and differs in several aspects compared to targeting to other compartments: (i) the sugarcane vacuolar compartment is highly dynamic in function, and is acidic as indicated by neutral red accumulation in most protoplasts isolated from sugarcane suspension cells and stem storage parenchyma cells (Gnanasambandam and Birch, 2004). It is not known whether several vacuole types coexist in sugarcane cells with different pH and/or proteolytic activities. As a result, there may be several independent targeting mechanisms to different vacuole types in sugarcane; (ii) targeted proteins should be stable and functional in the vacuolar environment, engineered for the relevant pH and proteases. For example, when the N-terminal vacuolar targeting signal (NTPP) of potato patatin was used to target yeast invertase to the sugarcane vacuole, neither detectable amounts of invertase protein nor increased soluble acid invertase activity was observed (Ma *et al.*, 2000). Similarly, fusion of NTPP from sweet potato sporamin to various reporter proteins resulted in substantial reduction or loss of enzymatic activity in transient expression assays and in transformed sugarcane cells (Gnanasambandam and Birch, 2004); and (iii) protein targeting mechanisms to many compartments (e.g., peroxisomes, mitochondria, and ER) are highly conserved in

eukaryotes. In contrast, protein targeting to the plant vacuole through the endomembrane system is different from the lysosomal and vacuolar targeting mechanisms of animals and yeast. While mammalian cells use mannose-6-phosphate mediated lysosomal targeting, yeast cells use N-terminal propeptides for vacuolar targeting. In contrast, plants employ three different types of targeting signals that are found either at the N-terminus or the C-terminus or within the mature polypeptide (Matsuoka and Neuhaus, 1999).

Two signals, the NTPP of sweet potato sporamin and sugarcane legumain, were reported to be efficient in targeting reporter proteins to the sugarcane vacuole (Gnanasambandam and Birch, 2004; Rae *et al.*, 2006). In contrast, the C-terminal signal from tobacco chitinase was inefficient in targeting a reporter protein to the sugarcane vacuole (Gnanasambandam and Birch, 2004). Using the NTPP of sporamin, metabolic engineering of vacuolar compartment to produce high-value isomaltulose has been demonstrated successfully (Wu and Birch, 2007). Vacuolar targeting of the sucrose isomerase using the NTPP of sporamin allowed high isomaltulose yields (up to 440 $\mu\text{mol g}^{-1}$ fresh weight) in sugarcane stems. In contrast, expression of a cytosolic form of the same enzyme caused stunting with reduced sugar accumulation. Interestingly, isomaltulose accumulated in storage tissues without any decrease in stored sucrose concentration, resulting in doubled total sugar concentrations in harvested juice (Wu and Birch, 2007) in vacuolar targeted lines. The transgenic lines with enhanced sugar accumulation also showed increased photosynthesis, sucrose transport and sink strength (Wu and Birch, 2007).

2.1.7.2 Protein targeting to plastids

The N-terminal plastid transit peptides of RbcS (rubisco small subunit) genes from maize and pea were used to target heterologous enzymes to sugarcane plastids to successfully produce *p*-hydrobenzoic acid (pHBA; McQualter *et al.*, 2005) and polyhydroxybutyric acid (PHB biopolymer; Petrasovits *et al.*, 2007). The transit peptides from tomato DCL (defective chloroplast and leaves) and tobacco RbcS genes were shown to target GFP to the sugarcane leaf proplastids (Gnanasambandam *et al.*, 2007; Figure 4).

2.1.7.3 Protein targeting to mitochondria

Mitochondria are important organelles involved in ATP synthesis, photorespiration, and programmed cell death. The N-terminal mitochondrial presequence from F₁-ATPase β -subunit (ATPase- β) of *Nicotiana glauca* was shown to be effective in targeting GFP to the mitochondria (Petrasovits *et al.*, 2007; Figure 4). Although this signal was used to target bacterial enzymes to sugarcane mitochondria, no PHB polymer accumulation was observed in transgenic sugarcane (Petrasovits *et al.*, 2007).

2.1.7.4 Protein targeting to peroxisomes

Plant peroxisomes are involved in fatty acid β -oxidation, the glyoxylate cycle and photorespiration. The six amino acid C-terminal peroxisomal signal from *Spinacia oleracea* L. (spinach) glycolate oxidase was shown to be effective in targeting GFP to the peroxisomes in sugarcane leaves and callus (Gnanasambandam *et al.*, 2008; Figure 4).

2.1.7.5 Protein targeting to ER

Almost all of the proteins that will be secreted to the cell exterior, as well as those destined for the lumen of the ER, Golgi apparatus, or vacuoles, are initially delivered to the ER lumen (Gal, 1998). The N-terminal ER signal peptide from *Arabidopsis* basic chitinase and a C-terminal HDEL signal for protein retention in the ER was efficient in targeting and retention of GFP in the ER in sugarcane leaves (Gnanasambandam *et al.*, 2007; Figure 4). This HDEL signal in combination with the ER signal peptide of *PinII* was required for higher accumulation of GM-CSF in transgenic sugarcane (Wang *et al.*, 2005a).

2.2 Target Traits and Products

For sugarcane genetic engineering, specific targets fall into two broad areas: (i) input traits that improve crop performance and productivity such as pest and disease resistance, tolerance to abiotic stress, herbicide tolerance, and alterations to plant

Figure 4 Confocal images of sugarcane leaf epidermal cells showing fluorescence of green fluorescent protein (GFP) in different subcellular compartments. Nontargeted GFP in the cytosol (a) and nucleus (arrow in a). ER-targeted GFP fluorescence in the ER (b, c; arrow in b shows perinuclear distribution). Plastid-, mitochondrial-, and peroxisomal-targeted GFP in the proplastids (d), mitochondria (e), and peroxisomes (f), respectively. All images show green channel GFP fluorescence except (c) and (d) that show merged images of green (GFP fluorescence) and red (chlorophyll autofluorescence) channels. Bar = 10 μ m [Reproduced with permission from Annathurai Gnanasambandam, BSES Limited, Australia]

architecture and (ii) output traits that modify quality and yield, compositions and use, such as production of more sucrose, biomass or novel compounds.

2.2.1 Disease resistance

Reports of pathogen-derived resistance to virus diseases include resistance to SCMV in otherwise susceptible sugarcane clones (Joyce *et al.*, 1998; Ingelbrecht *et al.*, 1999). Both groups used

the coat protein gene of the virus driven by the *Ubi-1* promoter with the *nos* terminator. Plants transformed with the coat protein gene of the SrMV strain SCH displayed a range of phenotypes, including immune, resistant, recovery, and susceptible plants, when challenged with virus. These observations enabled insights to the RNA-mediated PTGS resistance mechanism (Ingelbrecht *et al.*, 1999). Virus induced gene silencing (VIGS) has been suggested as the mechanism of resistance against viral infections. Interestingly, transgenic plants having the same

transgene integration pattern as determined by Southern blot analysis (i.e., clones) displayed a different response to mechanical SCMV infection. The reason for this peculiar result is still not clear (Ingelbrecht *et al.*, 1999).

Sugarcane yellow leaf disease, which is characterized by yellowing of the leaf midribs followed by tissue necrosis, is caused by ScYLV (Borth *et al.*, 1994; Schenck *et al.*, 1997; Vega *et al.*, 1997; Comstock *et al.*, 1998). Economic losses from sugarcane yellow leaf disease of up to 50% have been reported (Vega *et al.*, 1997). The ScYLV coat protein gene in the sense orientation driven by *Ubi-1* was used to generate virus-resistant transgenic sugarcane. Resistance levels were evaluated with inoculation of viruliferous aphids. Virus titers were determined using tissue blotting and quantitative reverse-transcriptase polymerase chain reaction (qRT-PCR). Two resistant transgenic sugarcane lines were identified based on the tissue blot analyses. However, virus RNA can still be detected using qRT-PCR in these lines. Greenhouse tests are currently being conducted to compare the yield difference between nontransformed and transgenic lines.

The transgenic approach for providing resistance to the more devastating viral disease in sugarcane, Fiji leaf gall has been tested (McQualter *et al.*, 2004). Resistance to Fiji leaf gall was produced by microprojectile-mediated transformation with a transgene encoding a translatable version of Fiji disease virus (FDV) segment 9 ORF 1 under the control of the maize *Ubi-1* promoter. The molecular phenotypes of the transgenic plants at both the DNA and RNA levels were not entirely consistent with a resistance mechanism based on PTGS. Transgenic plants showed very low steady state messenger-RNA (mRNA) levels under normal conditions, but many of these plants failed to show resistance upon challenge with the FDV virus, suggesting that the virus possessed a mechanism for overriding the post-transcriptional silencing mechanism. Further research required to achieve complete immunity to FDV includes: (i) additional characterization of the FDV genome, since only a superficial knowledge of the virus life cycle and replication strategy is currently known; (ii) a shotgun approach where all 12 ORFs contained within the FDV genome are used as transgenes, either singly or in various combinations (RNAi

(RNA interference) silencing constructs should be employed in this case); and (iii) determining if FDV possesses a dsRNA (double-stranded RNA) binding protein with the ability to suppress gene silencing. If so, then a more effective approach to achieve pathogen derived resistance to FDV in sugarcane might require deactivation of this protein.

Leaf scald is a serious disease of sugarcane caused by the bacterium *Xanthomonas albilineans*. The bacterium produces a toxin (albicidin) that blocks plastid DNA replication of the sugarcane plant. Zhang *et al.* (1999) identified a bacterium that could survive in the presence of albicidin because it carried an albicidin detoxification gene (*albD*). This gene was cloned from the bacterium and introduced into sugarcane. Some of the resulting transgenic plants were resistant to leaf scald disease (Hansom *et al.*, 1999). It is interesting to note that another bacterial pathogen of sugarcane *Leifsonia xyli* subsp. *xyli* (Lxx) like *Xanthomonas albilineans* colonizes the xylem vessels, was recently shown to have a gene homologous to the one in *Xanthomonas albilineans* encoding an enzyme to pump albicidin out of its cells (Monteiro-Vitorello *et al.*, 2004).

2.2.2 Insect resistance

The potential for using a modified *Bt* gene encoding the δ -endotoxin CryIA(c) from *Bacillus thuringiensis* strain *kurstaki* to combat damage by the lesser corn-stalk borer (LCB) was demonstrated by Fitch *et al.* (1996). The *Bt* gene and the selectable marker gene *nptII*, were under the control of the CaMV 35S promoter. Bombarded sugarcane calli were selected stepwise on 50–200 mg l⁻¹ of G418, an aminoglycoside antibiotic similar in structure to gentamicin B1. Insect bioassays indicated that LCB larvae fed on some lines of calli or leaves from the regenerated plants weighed less and showed higher mortality than those fed on nontransgenic tissues. Mortality was higher when LCB were fed transgenic calli as opposed to transgenic leaves, possibly due to different levels of the CryIA(c) protein in the two different tissues, although the protein levels were not reported. Leaves from other putatively transformed lines had no detectable effect on larvae survival. Southern hybridization indicated

that there were 1–5 copies of the *Bt* genes in the two most resistant lines.

Resistance to the other lepidopteran sugarcane stalk borers has also been reported using the δ -endotoxin gene from *B. thuringiensis*. Larval mortality and reduced levels of damage from *Diatraea saccharalis* in the field and *Proceras venosatus* in the glasshouse have been reported (Arencibia *et al.*, 1997; Weng *et al.*, 2006). In the short term, it is possible that intellectual property restrictions may limit widespread use of this technology in sugarcane. Consequently, the use of other antimetabolic compounds for improving plant resistance, such as proteinase inhibitors (Allsopp *et al.*, 1996; Falco and Silva-Filho, 2003) and lectins (Sétamou *et al.*, 2002a, b, c), has been tested with promising results from laboratory-based insect bioassays. These products impact on a wider range of insect/pests and studies on the effects on the Australian coleopteran whitegrub have been underway for several years (Allsopp *et al.*, 1996).

Canegrubs are a major pest in the Australian sugar industry causing yield losses up to AU \$80 million. The *PinII* and the snowdrop lectin (*Gna*) genes have both been used to generate transgenic sugarcane in attempts to control these pests (Allsopp *et al.*, 1996; Nutt *et al.*, 1999). Plants containing the *pinII* gene grew more slowly than the nontransformed control plants. This may have been due to metabolic disruption within the plants, as no *pinII* was found in the cell vacuole. Earlier work with artificial feeding trials had shown that avidin could reduce larval growth and increase larval mortality of *Antitroglus parvulus* (Childers canegrub) (Allsopp and McGhie, 1996). More recently, the gene for avidin, a biotin binding protein from chicken egg white, has been introduced into sugarcane for the control of canegrubs (Nutt *et al.*, 2006). Transgenic sugarcane plants have been regenerated, which contain avidin concentrations of up to 0.06% of total protein.

2.2.3 Sucrose metabolism

A suite of physiological processes and enzymes involved in sucrose accumulation have been identified and characterized over the last 50 years. These processes include: leaf reactions,

such as photosynthetic reactions, sucrose synthesis, metabolism and carbon partitioning across various membranes into different pools; phloem reactions, such as phloem loading in leaf, translocation to and unloading in various sink tissues (including primary storage in parenchyma cells of the stalk); stalk reactions, such as membrane transport, sucrose metabolism, carbon partitioning, and remobilization of stored sucrose; genetic and developmental controls, such as timing of maturation; and environmental perception and signal transduction pathways to coordinate plant development (Moore, 2005). Some of the genes encoding these enzymes have been cloned and used to transform sugarcane with the goal of altering sucrose accumulation (reviewed by Grof and Campbell, 2001). However, this reductionist approach has fallen short of expectation in almost all of the cases because of the complexity among the multitude of simultaneous processes and parallel pathways.

As tissue culture methods became established, they were exploited to elucidate the physiology and biochemistry of sugarcane carbohydrate accumulation, with particular emphasis on sugars (Komor *et al.*, 1981; Thom and Komor, 1984). Transgenic sugarcane cell lines were also used to study the effect of invertase expression in different cellular compartments on sucrose accumulation (Ma *et al.*, 2000). Overexpression of a yeast invertase gene (*SUC2*) in the apoplast led to rapid hydrolysis of sucrose and accumulation of hexoses, both in the medium and the cells, suggesting that hexose uptake, not hexose availability, was the limiting factor for sucrose accumulation. Cells transformed for overexpression of invertase in the cytoplasm did not show a significant change in the sugar composition in the medium, but did significantly reduce the sucrose content in the cells. Partial inhibition of the soluble invertase activity was achieved by transforming with a sugarcane soluble acid invertase complementary DNA (cDNA) (*SCINVm*) in the antisense orientation to result in increased sucrose accumulation. Intra- and extra-cellular sugar composition was very sensitive to changes in invertase activities in this tissue culture system (Ma *et al.*, 2000).

Pyrophosphate-dependent phosphofructokinase (PFK) activity in sugarcane is inversely correlated to sucrose concentration in maturing internodal tissues, but no clear physiological role

in sucrose metabolism has emerged (Whittaker and Botha, 1999). If endogenous PFP activity were to be down-regulated by antisense or co-suppression technologies, then sucrose concentration could be increased. In sugarcane transformed with the catalytic subunit, PFP- β , endogenous PFP gene expression was reduced by up to 40% and 80% in leaf roll and internodal tissue, respectively (Groenewald and Botha, 2001, 2008). Sucrose concentrations in these lines were significantly increased in immature internodes. This finding could make a valuable contribution to the productivity of sugarcane cultivars and elucidate the role of PFP in sucrose accumulation.

Vickers *et al.* (2005a) attempted to modify the endogenous polyphenol oxidase (PPO) activity in sugarcane by introducing sense and antisense constructs of the endogenous sugarcane PPO gene driven by the *Ubi-1* promoter. The rationale behind this approach was that the inhibition of PPO activity in juice by chemical inhibitors, elevated pH or heat significantly reduced the color of the cane juice and the subsequent color intensity in sugar crystals. All transgenic lines, irrespective of the orientation of the PPO gene, showed higher PPO activity and more color units than the nontransformed commercial clones. Although higher levels of PPO activity were correlated to juice with a darker color, the converse was not true in this study. It has been hypothesized that a lowering of PPO activity will lead to a reduction in the color of juice and consequently raw sugar (Vickers *et al.*, 2005a). As pale sugar has a market premium over dark sugar, this has potential economic benefits for the sugar industry.

While most transgenic attempts to improve sugar accumulation in sugarcane have met with limited success, a notable exception was the introduction of a bacterial gene encoding a sucrose isomerase (Wu and Birch, 2007) to produce a high-value sugar isomaltulose.

2.2.4 Alternative products

High-value sugars. Isomaltulose is a sucrose isomer with α -1,6 linkages instead of α -1,2. Although it is only 42% as sweet as sucrose (Li *et al.*, 2004), it is a high-value sugar because it is digested 4–5 times slower than sucrose and so

has major health benefits to consumers (Lina *et al.*, 2002). Not only does isomaltulose reduce the highs and lows in blood sugar (Lina *et al.*, 2002), it also has dental health benefits (Ooshima *et al.*, 1983). Wu and Birch (2007) demonstrated that sugarcane can be engineered to target the production of isomaltulose in the storage vacuoles in sugarcane stalks (see Section 2.1.7). In transgenic lines, when sucrose isomerase was targeted to the vacuole, isomaltulose accumulated without a reduction in sucrose accumulation. Up to a two-fold increase in total sugar accumulation was observed in some lines (Wu and Birch, 2007). The additional sugar was not produced at the expense of structural carbohydrates, as levels of fiber were the same between wild type and transgenic lines. Additional benefits were that the levels of isomaltulose reduced leaf senescence resulting in more leaf biomass on the plants and a reduction in the percent water in stalk tissue from 70% for the nontransformed control mature stalk internode to 60% in the best isomaltulose producing transgenic line (Wu and Birch, 2007). Field trials of these high-sugar lines are currently underway.

Sorbitol. The primary photosynthate of the members of the Rosaceae family including apples (*Malus domestica*), pears (*Pyrus* sp.), peaches and nectarines (*Prunus persica*), plums (*Prunus* subgenus *Prunus*), cherries (*Prunus* subgenus *Cerasus*) is sorbitol. Sorbitol has intrinsic value as a noncaloric sweetener and is also used to manufacture ascorbic acid and personal care products (Kirschner, 2004). Sorbitol synthesis in sugarcane is achieved by a single enzyme conversion step sorbitol-6-phosphate dehydrogenase (S6PDH), which catalyzes the reduction of D-glucose-6-phosphate (G6P) to sorbitol-6-phosphate (S6P). The cytosolic expression of the *M. domestica* sorbitol-6-phosphate dehydrogenase gene (*mds6pdh*) resulted in high accumulation of sorbitol (up 61% of the soluble sugars or 12% of the leaf dry weight) in sugarcane leaves but with 10-fold less sorbitol in the culm (Chong *et al.*, 2007; Brumbley *et al.*, 2004). Sugarcane leaves developed necrosis in a pattern characteristic of early senescence and the severity was related to the relative quantity of sorbitol accumulated. Vacuolar targeting of the same enzyme, while not attempted, may lead to normal plants and higher accumulation of sorbitol in the culm as observed for isomaltulose (Wu and Birch, 2007). However,

Figure 5 PHB sugarcane line TA4 cells showing plastids containing polyhydroxybutyrate granules. Six-month-old sugarcane plants were sectioned and analyzed for PHB content in (a) leaf tissue taken from the midrib of the lowest green leaf and sampled from older tissue closest to the leaf tip, (b) stem tissue sampled from the basal internode, (c) stem tissue sampled from the basal node. Black and white arrows point to clusters of PHB granules [Reproduced with permission from Todd Werpy and Gene Petersen, the lead authors of “Top Value Added Chemicals from Biomass”. <http://www1.eere.energy.gov/biomass/pdfs/35523.pdf>]

protein stability within the vacuole will continue to be a major challenge for efficient metabolic engineering of the sugar storage compartment in sugarcane. A possible solution would be to modify the enzymes, possibly by using directed evolution (Stemmer, 1994a, b; Chica *et al.*, 2005; Kaur and Sharma, 2006) to function optimally at the pH and to be more resistant to the protease activity in the environment of the storage vacuole.

In addition to the above mentioned sugars, trehalose, a nonreducing disaccharide of glucose, has also been produced in sugarcane (Brumbley *et al.*, 2006b; O'Neill *et al.*, 2006; Zhang *et al.*, 2006). Trehalose may play a role in carbohydrate metabolism impacting on glucose, fructose, and sucrose levels (Rontein *et al.*, 2002).

Biopolymers. To test the ability of sugarcane to be a biofactory, the products from the *Ralstonia eutropha* PHB biosynthetic pathway were targeted to several subcellular compartments of sugarcane (Brumbley *et al.*, 2002, 2004, 2007; Petrasovits *et al.*, 2007; Purnell *et al.*, 2007). PHB is the best-studied member of the polyhydroxyalkanoate (PHA) family, of which approximately 130 naturally occurring members have been identified (see Section 3). PHB is produced from acetyl-coenzyme A (acetyl-CoA) by the successive action of three enzymes [ketothiolase (PHAA), acetoacetyl-reductase (PHAB), and PHB synthase (PHAC)], which are encoded by the genes *phaA*, *phaB*, and *phaC*, respectively (Peoples and Sinskey, 1989a, b). Each gene was on a separate transformation vector and gene expression was controlled by *Ubi-1* promoter and *nos* terminator sequences. The three vectors with the PHB biosynthetic pathway were

biologically transformed into sugarcane callus simultaneously along with a construct containing the selectable marker gene *nptII* (Petrasovits, 2005; Petrasovits *et al.*, 2007).

Previous attempts to produce PHB at high levels in plants resulted in either low levels of PHB accumulation or severe negative phenotypic effects. In sugarcane, the polymer accumulated in the leaves of chloroplast-targeted lines at levels up to 2.5% of dry weight and 0.01% in stems (Figure 5) (Petrasovits *et al.*, 2007). Purnell *et al.* (2007) conducted a replicated glasshouse trial using a random block design with six independent PHB producing transgenic sugarcane lines and found that stalk height and weight and sugar levels were not affected by PHB accumulation.

Sugarcane has also been evaluated as a production platform for *p*-hydroxybenzoic acid (pHBA) using two different bacterial proteins (a chloroplast-targeted version of *E. coli* chorismate pyruvate-lyase and a 4-hydroxycinnamoyl-CoA hydratase/lyase from *Pseudomonas fluorescens*) (McQualter *et al.*, 2005; Brumbley *et al.*, 2004). Both lines provide a one-enzyme pathway from different naturally occurring plant intermediates. The substrates for these enzymes are chorismate (a shikimate-pathway intermediate that is synthesized in plastids) and 4-hydroxycinnamoyl-CoA (a cytosolic phenylpropanoid intermediate). Although both proteins have previously been shown to elevate pHBA levels in plants (Siebert *et al.*, 1996; Mayer *et al.*, 2001), they had never been evaluated concurrently nor had they been used simultaneously in the same plant. The pHBA was quantitatively converted to glucose

conjugates by endogenous uridine diphosphate (UDP)-glucosyltransferases and was stored in the vacuole. The largest amounts detected in leaf and stem tissue were 7.3% and 1.5% of dry weight (DW), respectively, and there were no observable phenotypic abnormalities. However, as a result of diverting carbon away from the phenylpropanoid pathway, there was a reduction in leaf chlorogenic acid, subtle changes in lignin composition, and an apparent compensatory up-regulation of phenylalanine ammonia-lyase (PAL; McQualter *et al.*, 2005).

2.2.5 High-value protein production

GM-CSF, which is used in clinical applications for treatment of neutropenia and aplastic anemia, was used to test the feasibility of using sugarcane as a biofactory for high value protein production (Wang *et al.*, 2005a). Two promoters, *Ubi-1* and sugarcane *ubi9* were tested in transgenic sugarcane lines resulting in production of up to 0.02% total soluble protein as GM-CSF. No significant difference was observed between the *Ubi-1* or *ubi9* promoter line. To achieve higher accumulation of GM-CSF in sugarcane, a C terminal HDEL tag for ER targeting had to be added to the gene construct. The sugarcane-produced GM-CSF showed identical biological activities when compared to commercially available purified protein. In a 14-month old field trial, no abnormal phenotype was observed and the accumulation levels remained relatively stable. This is the first report of GM-CSF production in field-grown plants. No flowering of the trial plants occurred and no pollen or seed was produced during the trial period. Drying, burning, and burial of the test plants effectively blocked possible routes for the transgenic sugarcane to enter the food supply or environment. If GM-CSF accumulation in sugarcane had been as high as Sétamou *et al.* (2002c) reported for the snowdrop lectin (1–1.25% total soluble protein), commercial production would probably have been economically viable because of the high commercial value of this protein.

Sugarcane has also been used for the production of bulk protein, collagen. In vertebrates, the collagen family is made up of approximately 27 proteins (Myllyharju *et al.*, 2000; Kielty and

Grant, 2002; Gelse *et al.*, 2003; Myllyharju and Kivirikko, 2004; Pakkanen *et al.*, 2006). Collagens make up 25% of the total proteins in humans and function to act as connecting structures and to give mechanical stability to the entire body. They form triple-helical structures, giving them commercial importance for the food industry and for a range of medical applications, such as tissue repair and cosmetic surgery (Bulleid *et al.*, 2000). Gelatin is denatured collagen. The yeast *Pichia pastoris* has been engineered successfully for the high level production of triple-helical collagen (Pakkanen *et al.*, 2006). Production has also been attempted in sugarcane and a fragment of human collagen was produced at very low levels (0.025% total soluble protein) (E. Mirkov, personal communication).

2.2.6 Abiotic stress

One strategy for generating abiotic stress-resistant plants has been to express genes for the production of trehalose. *In planta* trehalose production confers stress tolerance in plants (Garg *et al.*, 2002; reviewed in Penna, 2003; Rolland *et al.*, 2006). Abiotic stress normally causes a reduction in photosynthesis. However, trehalose protects the photosynthetic machinery in the plant cells and allows them to remain functional for longer periods of time under a range of abiotic stress conditions (Garg *et al.*, 2002; Rolland *et al.*, 2006). By using two copies of the CaMV 35S promoter in tandem to drive expression of the *Grifola frondosa* trehalose synthase gene in *S. officinarum*, Zhang *et al.* (2006) achieved trehalose accumulation in sugarcane cells at 0.9–1.2% of fresh weight. This low-level production in transgenic plants has been seen in other plant species and has been attributed to native trehalase activities (Garg *et al.*, 2002; Penna, 2003). The transgenic lines showed no negative effects on growth, were drought tolerant, and produced higher yields under drought conditions.

2.2.7 Flowering

In sugarcane cultivars, the time and intensity of flowering are important as they influence the yield and quality of cane (Premachandran, 2006). Sugarcane yield is reduced by cessation of vegetative growth in flowering canes and profusely

flowering clones are undesirable for commercial cultivation, especially when used for late-season crushing.

The identification of genes with major effects on flower induction could lead to new ways to control flowering in sugarcane cultivars (Ulian, 2006). Flower formation depends on the transition of a vegetative meristem to an inflorescence meristem and, subsequently, to a floral meristem. This transition requires the action of a number of genes, including *LEAFY* (*LFY*), a gene that is expressed early and considered to be important in the flowering process (Weigel *et al.*, 1992). *LFY* interacts with another floral control gene, *APETALA1* (*API*), to promote the transition from inflorescence to floral meristem. The ectopic expression of *LFY* induces the ectopic expression of *API* in leaf and axillary flower primordia (Parcy *et al.*, 1998). *LFY* and *API* are pivotal for the switch to the reproductive phase, where, instead of leaves, the shoot apical meristem produces flowers. The *API* promoter is a direct target of *LFY* (Wagner *et al.*, 1999). *LFY* also directly targets the *AGAMOUS* (*AG*) promoter that contains a *LFY*-responsive enhancer necessary for its activity (Busch *et al.*, 1999). *AG* encodes a transcription factor that regulates genes determining stamen and carpel development in wild-type flowers (Yanofsky *et al.*, 1990). *LFY*, therefore, plays pivotal roles in the specification of flowers and in the patterning of floral organs (Hempel *et al.*, 2000).

To study flowering in sugarcane, Ulian (2006) analyzed the SUCEST database and found a DNA EST with significant similarity to the *Arabidopsis* *LFY* sequence with two regions highly conserved in the *LFY* family of transcription factors. The putative *LFY* gene from sugarcane was expressed in the antisense orientation in transgenic sugarcane clone SP87-432 under the control of the constitutive maize *Ubi-1* promoter. Ulian (2006) observed that silencing of the *LFY* gene suppressed flowering in transgenic sugarcane, supporting the notion that the gene plays an important role in sugarcane flower development.

3. FUTURE ROAD MAP

Recent research on sugarcane has started to produce the detailed biochemical and genetic information that will be needed to develop

technologies necessary for sugarcane improvement and to metabolically engineer sugarcane for various traits and compounds.

3.1 Expected Technologies

To successfully manipulate the metabolic processes in sugarcane, a combination of molecular tools is required. In addition, consideration has to be given to both the organizational complexity at the whole plant level and the metabolic compartmentation within cells. Metabolic engineering requires a transformation system, suitable gene(s) and vector constructs, appropriate promoter sequences for cell- and tissue-specific expression, and effective targeting signals to direct the protein to its final destination within the cell. In sugarcane, an efficient transformation system (Bower and Birch, 1992; Bower *et al.*, 1996) and effective targeting signals to direct heterologous proteins to various compartments including the vacuoles, plastids, and mitochondria are available (Gnanasambandam and Birch, 2004; McQualter *et al.*, 2005; Rae *et al.*, 2006; Petrasovits *et al.*, 2007; Gnanasambandam *et al.*, 2007). Future research should focus on improving the efficiency of existing technologies as well as developing new technologies.

3.1.1 Improved nuclear transformation efficiency

Currently, the biolistic method is the most efficient method for the production of transgenic sugarcane plants (Bower and Birch, 1992). However, transformed plants obtained through this method have several shortcomings, including the presence of numerous copies of transgenes with complex patterns of integration (Albert *et al.*, 2003; Wang *et al.*, 2003). This creates some difficulties in obtaining regulatory approval for transgenic crop plants. Multiple transgene integrations may also inhibit transgene expression, cause gene silencing, and/or promote transgene rearrangements. Additionally, biolistic transformation entails incorporation of the entire plasmid into the plant nuclear genome, which is a cause for public concern. Thus, genes essential for plasmid replication (*ori*) in bacteria as well as

antibiotic resistance (e.g., ampicillin) required for selection of the transformed bacterial colony are co-introduced along with the gene(s) of interest. To minimize these problems, two technologies are currently being tested—*Agrobacterium*-mediated transformation (see Section 2) and the use of linearized plasmid DNA (LDNA) containing only the promoter-ORF-terminator cassette.

Agrobacterium-mediated transformation generally produces transgenic plants with fewer copies of the transgenes. *Agrobacterium*-mediated transformation of sugarcane has been reported in a few laboratories (Section 2). Most reports in sugarcane have shown the number of transgene copies to be generally between one and three (see Section 2). This may lead to higher and more stable expression of the transgenes as has been reported in rice (Dai *et al.*, 2001) and maize (Shou *et al.*, 2004) when compared to biolistic transformants. However, the stability of transgene expression using *Agrobacterium*, compared to biolistic transformation, has yet to be verified in sugarcane. Also, the efficiency of transformation is comparatively lower than that for microprojectile bombardment. Future research must aim to increase the efficiency of this transformation method in sugarcane.

In *Agrobacterium*-mediated transformation, transfer of genes of interest (present in the T-region of the *Ti* plasmid of *Agrobacterium*) into the plant nucleus usually occurs between the right and left T-DNA (transfer DNA) borders of the plasmid (Hellens *et al.*, 2000). Generally, this region only contains the regulatory sequences along with the genes of interest. Thus, the transfer is believed to be precise, with none of the plasmid sequences flanking the border regions being transferred. Recently, however, Shou *et al.* (2004) analyzed transgenic maize to determine whether vector backbone sequences of the *Ti* plasmid were also transferred. They showed that in 75% of the R_1 progeny of primary transformants there was some portion of the backbone present. This event may have occurred due to the specific transformation conditions used in the experiment. This needs to be determined when transforming sugarcane with *Agrobacterium*. Field trials of sugarcane plants transformed with *Agrobacterium* are proposed to commence in Australia in 2007 to address many of the concerns raised above (P. Joyce, personal communication).

Concerns raised by activists regarding the release of microbial genes into the environment coincidently with the biolistic transformation procedure has led scientists to use LDNA containing only the promoter-ORF-terminator cassette region for plant transformation. This LDNA method has been tested for gene expression and copy number analysis in rice (Fu *et al.*, 2000; Loc *et al.*, 2002). There was a significant reduction in the number of copies integrated into the rice genome. In addition, a low frequency of transgene rearrangements without any deleterious effect on expression pattern was observed (Fu *et al.*, 2000). Moreover, when two minimal linear genes were co-bombarded, the co-transformation efficiency was similar to that using intact circularized plasmids. Similar experiments in sugarcane, however, showed that it behaved differently to rice (Albert *et al.*, 2004; Joyce *et al.*, 2006b).

3.1.2 Plastid transformation

The current nuclear transformation technology has several limitations, including semi-random and unpredictable incorporation of foreign genes into the genome, and the operation of genetic mechanisms that can switch off foreign genes, resulting in widely varying expression of introduced genes in sugarcane (Ingelbrecht *et al.*, 1999; Gilbert *et al.*, 2005; Vickers *et al.*, 2005a, b). A powerful new strategy, plastid transformation, has been developed in some plants, including *Arabidopsis*, tomato, potato, cotton, carrot, and rice (Bock and Khan, 2004; Koya *et al.*, 2005), with the potential to circumvent these problems by introducing genes into plastid DNA rather than the plant nuclear genome (Maliga, 2002; Daniell *et al.*, 2005b). The plastid transformation strategy utilizes two targeting sequences that flank the foreign genes and that inserts them through homologous recombination at a precise, predetermined location in the chloroplast genome (Maliga, 2004).

Transformation of sugarcane plastid genome (plastome) offers several advantages over nuclear transformation. These include, but are not limited to:

1. High levels of protein production: Because each leaf cell may contain up to 10 000 copies of plastid DNA (each green cell contains

about 50–100 chloroplasts with 60–100 plastid genomes per plastid), plastid-transformed tobacco plants synthesize extraordinary levels of foreign proteins (e.g., 5% of *Bt* toxin that provides resistance against insect pests (McBride *et al.*, 1995)). This concentration is about 10-fold higher than the maximum achieved following transformation of the plant nuclear genome. These high levels of protein production in the plastids can facilitate the development of genetically improved sugarcane plants resistant to insect pests or herbicide damage, and the use of sugarcane plants as efficient bioreactors for production of novel high value biochemicals, pharmaceuticals, and industrial materials (Guda *et al.*, 2000; DeGray *et al.*, 2001; Daniell *et al.*, 2005a).

2. Consistent gene expression: Protein expression from a gene inserted at a specific site in the plastid genome will be more consistent within the leaves of different transformants (Maliga, 2004).
3. Significantly reduced risk of spread of foreign genes (biocontainment): Chloroplasts are predominantly inherited through the maternal line in most important agricultural plants. Hence, the risk of a foreign gene being transmitted in pollen to nontransgenic sugarcane crops or related species is minimal (Lee *et al.*, 2006). This has been experimentally shown by the containment of herbicide resistance in tobacco (Daniell *et al.*, 1998)
4. Absence of gene silencing: Foreign genes can be silenced in sugarcane plants by modification of the inserted DNA in the nucleus, or by specific breakdown of the corresponding mRNA required as a template for protein synthesis in the cytosol. As there are no known similar silencing mechanisms identified in plastids (Dhingra *et al.*, 2004; Lee *et al.*, 2003a), foreign genes should be exempt from silencing in plastid transformed sugarcane plants, in which both transcription and translation occur within the chloroplast, separated from the cytosol.
5. The ability to express polycistronic messages from a single promoter: In nuclear transformation, each encoding sequence must be engineered under the control of a separate

regulatory region, i.e., a monocistron. As a consequence, gene expression levels vary widely among introduced sequences, and generation of a number of transgenic plant lines is required to introduce all of the cistrons into one plant and to get proper coordinated expression in the target biochemical pathway. In contrast, the functioning of the plastid genome (being prokaryotic in nature) permits simultaneous expression of two or more genes from a single plastid promoter region (Quesada-Vargas *et al.*, 2005). Such an expression method makes possible large scale and inexpensive production of some proteins and fine chemicals. In addition, it allows the engineering of metabolic pathways through the introduction of multiples genes in a single operon.

6. Integration via a homologous recombination process that facilitates targeted gene replacement and precise transgene control.
7. Sequestering of foreign proteins in the organelle, which prevents adverse interactions with the cytoplasmic environment. In addition, the ability of chloroplasts to form disulfide bonds and to fold human proteins could allow high-level production of biopharmaceuticals in plants.

Despite its tremendous biotechnological potential, plastid transformation has only been used routinely in tobacco (Maliga, 2004) and attempts to develop plastid transformation in sugarcane have been unsuccessful to date. However, a recent patent issued on plastid transformation in monocots (Daniell, 2006) indicates the potential exists to develop the technology in sugarcane. The complete nucleotide sequence of the chloroplast genome of sugarcane has been determined recently (Asano *et al.*, 2004). The plastome of sugarcane is a circular double-stranded DNA molecule, 141 182 bp in size, and is composed of a large single copy of 83 048 bp, a small single copy of 12 544 bp, and a pair of inverted repeat regions of 22 795 bp each. The sugarcane chloroplast genome is similar to maize, but not to rice or wheat. The availability of sequences for sugarcane chloroplast genome (Asano *et al.*, 2004) could facilitate the development of plastid transformation technology in sugarcane.

3.1.3 Avoiding antibiotic resistance gene in transgenic plants

Elimination of antibiotic resistance selectable marker genes in transgenic plants may increase public acceptance of this technology. The options available include:

1. Use of no selectable marker gene, i.e., only the gene of interest is introduced and transformed tissue is screened for (not a practical solution due to time constraints).
2. Use of a visual marker gene such as *GFP* (which has no harmful biological activities) to select transformed cells (Elliott *et al.*, 1998), which can be cumbersome and prone to contamination.
3. Selecting T₁ progeny that do not contain the antibiotic resistance gene, i.e., they have segregated for the antibiotic resistance gene. This is not an option for sugarcane, because none of the commercial sugarcane cultivars are homozygous. Sugarcane clones are clonally propagated to maintain the elite characters.
4. Use of an antibiotic gene excision system; once again, this will involve retransformation of transgenic cane. However, if more inducible promoters were available, it would be possible to control excision of the antibiotic gene (after selection and regeneration of plants) by switching on the expression of the site-specific recombinase gene (Puchta, 2000).
5. Use of a selection system that is not antibiotic based. The use of alternative marker genes conferring positive selection. For instance, a nontoxic compound to promote the regeneration and growth of transformed cells expressing a transgene that acts upon that compound are being developed. It may even be possible to tailor-make genes that are designed to specific plants.
6. Sugarcane plastid transformation would be one possible way of removing both antibiotic resistance genes and vector sequences from plants using homologous recombination.
7. Bombardment with linear DNA avoids vector-localized genes such as the ampicillin resistance (see Section 3.1.1). Transformation of sugarcane with linearized DNA fragments has been demonstrated (Joyce *et al.*, 2006b).

3.1.4 Suppressing transgene silencing

There are convincing reports indicating that sugarcane displays a high level of PTGS (Liu *et al.*, 2003; Wei *et al.*, 2003). Strategies to suppress this include the use of viral suppressor proteins (Mangwende *et al.*, 2005), addition of putative matrix attachment regions (MARS) (Wei *et al.*, 2003), and presence of introns. The use of viral suppressors, including P0 from ScYLV and HcPro from SrMV, to advance our knowledge of RNA silencing in sugarcane are being explored (Wang *et al.*, 2006, 2007). More research is needed to understand and suppress transgene silencing.

3.1.5 Tissue-specific promoters

Despite several years of research, an effective stem-specific promoter is not yet available in sugarcane. Though a stem-specific promoter has been reported in sugarcane (Hansom *et al.*, 1999), its usefulness remains to be established. Similarly, other tissue-specific promoters that are operative in sugarcane (for example, root-specific promoters) are not available. Attempts to find new promoters for strong expression especially in the mature parenchyma cells of sugarcane stem are ongoing. Recently, Mudge *et al.* (2006) reported the isolation of an EST clone (SMS04) that was selected based on its expression pattern. Further analysis revealed that at least eight variants of this gene existed in sugarcane and that no two had the same sequence. The promoters associated with these genes were isolated and activity tested using the *GUS* reporter gene. Most were functional soon after introduction into the explant, but none maintained activity in mature regenerated plants.

To avoid gene silencing, Potier *et al.* (2006) isolated tissue-specific promoters from the upper stem or roots of maize and sorghum rather than sugarcane. These promoters (with and without the first intron) were used to test the expression of *GUS* gene in sugarcane callus. In general, the presence of an intron showed higher expression in all the promoters studied. Further research should identify effective tissue-specific promoters that can maintain activity in mature transgenic plants. With the available sorghum genome sequences, the search and solution to finding new tissue-specific promoters is more tangible.

3.1.6 Transcriptional regulators

Transcription factors are proteins that interact with the promoter regions of target genes in a sequence-specific manner. They influence the manner in which RNA Polymerase II initiates mRNA synthesis by enhancing or repressing gene expression and, hence, are important regulators of gene expression. Transcription factors tend to control multiple steps in metabolic pathways, meaning that a single protein can affect the expression pattern of a large number of downstream genes (Kinney, 2006). This is an important consideration for plant transformation strategies aimed at significantly affecting the level of end-product accumulation. Although this can be a successful strategy, a lack of knowledge about a particular pathway may mean that additional and hitherto unknown rate-limiting steps may be present that may frustrate the attempt to significantly modify end-product accumulation. Overexpression of transcription factors holds the promise of significantly altering the overall flux through a metabolic pathway by controlling the transcription of multiple genes. The potential of using transcription factors to enhance current and future work into the genetic enhancement of sugarcane is highlighted in Sections 2.2.6, 3.2.6, 3.2.7, and 3.2.9.

3.1.7 Modifying more complex traits

Very few traits that are simply-inherited have been described in sugarcane (Hogarth, 1987; Daugrois *et al.*, 1996; Mudge *et al.*, 1996a, b; Raboin *et al.*, 2006), suggesting that most phenotypic characteristics, such as cane yield and sugar content, are controlled by polygenes. In other organisms, genes that contribute to complex traits (QTL) pose special challenges that make gene discovery and subsequent modification of such traits more difficult. Such problems include locus heterogeneity, epistasis, low penetrance, variable expressivity, and pleiotropy (Glazier *et al.*, 2002). Approaches are even more difficult in sugarcane, where there is the possibility of segregation for three or more alleles at a locus, a lack of chromosome preferential pairing and high levels of heterozygosity (Ming *et al.*, 2001a, b; Aitken *et al.*, 2006), which generally results in numerous

alleles of small effect, some of which cannot be positioned on a genetic map. These factors work together to make claims of linkage discovery notoriously difficult to verify and candidate gene identification challenging. However, prospects for success can be improved through genome sequencing and comparative genomics. Such resources will allow more rapid dissection of complex traits through candidate gene identification and subsequent testing using functional genomics approaches.

3.1.8 Functional and comparative genomics

3.1.8.1 Expressed sequence tags (ESTs)

Sequencing efforts by different organizations in several countries have provided a large set of publicly available ESTs in sugarcane (Carson and Botha, 2000; Casu *et al.*, 2003; Vettore *et al.*, 2003; Ma *et al.*, 2004). The largest of these efforts was undertaken in Brazil by the Organization for Nucleotide Sequencing and Analysis (ONSA). A network of laboratories in all the major research institutions across the state of São Paulo conducted genomics and transcriptomics (Harvey and McMeekin, 2005) on sugarcane ESTs (SUCEST) (<http://sucest.lad.dcc.unicamp.br/en>). The goal of the SUCEST project was to identify 50 000 sugarcane genes or generate a total of 300 000 ESTs. Following sequencing, the data mining groups in SUCEST worked on a cross-section of sugarcane genes including, but not limited to genes involved in amino acid metabolism, carbohydrate metabolism, lipid metabolism, energy metabolism, metabolism of co-factors (vitamins and other substances), nutrient uptake and metabolism, environmental stress, pathogenesis, membrane receptors, phytohormone biosynthesis and regulation, plant morphology, flowering and development of reproductive organs, patterns and levels of gene variation, and comparative genomics.

The outcomes of the SUCEST project were significant. It established Brazil as a biotechnology innovator, developed skills and capabilities throughout research institutions in São Paulo, created international collaborations and networks, and resulted in the formation of new biotech companies (Harvey and McMeekin,

2005). Data from the SUCEST project, and from other sequencing efforts, has been centralized at the Institute for Genomic Research's (TIGR) *Saccharum officinarum* Gene Index (SoGI) (http://www.tigr.org/tigr-scripts/tgi/T_index.cgi?species=s_officinarum; Quackenbush *et al.*, 2001). TIGR aims to integrate research data from international sugarcane EST sequencing and gene research projects. Its ultimate goal is to represent a nonredundant view of all sugarcane genes and data on expression patterns, cellular roles, functions, and evolutionary relationships. The TIGR database has 255 635 ESTs with a total of 78 547 unique sequences. This database was recently moved to the Computational Biology and Functional Genomics group at Harvard University, where it is incorporated into an even bigger gene index project: <http://compbio.dfci.harvard.edu/tgi/plant.html>.

A subset of the available EST sequences have been arrayed on a Sugar Cane GeneChip[®] (Affymetrix) (Casu *et al.*, 2006), which is designed specifically to monitor gene expression. The GeneChip[®] Sugar Cane Genome Array contains 8236 *S. officinarum* probe sets to monitor gene expression for approximately 6024 distinct genes. Expression profiling using this and other cDNA arrays, along with mapping studies, have investigated genes involved in stem development, sugar accumulation, growth at low temperatures, and disease resistance (Casu *et al.*, 2003, 2004, 2005, 2006; Nogueira *et al.*, 2003; Rossi *et al.*, 2003). These, and future studies, should provide targets for functional genomic screens through either overexpression or RNAi-mediated gene knockout strategies. In fact, field testing of a number of lines for increased sugaryield has already begun by the Centro de Tecnologia Canavieira (CTC) and Allelyx, a biotech start up company developed out of the ONSA genomics program (Harvey and McMeekin, 2005).

Importantly, the wealth of sequence information available allows for a robust strategy to incorporate all polymorphic alleles. The EST database is also a starting point for metabolic engineering by helping to understand sugarcane central metabolism. For instance, in a recent approach to produce trehalose in sugarcane, a survey of the EST collection identified a probable trehalose dehydrogenase, the activity of which would have to be inhibited for the strategy to be successful (O'Neill *et al.*, 2006).

3.1.8.2 Genomics

The large database of public ESTs described above is an important resource that has been useful in a variety of ways, providing functional DNA markers, a foundation for development of expression profiling platforms, and a rich resource for evolutionary studies. Available EST sequences may collectively provide tags for half of the sugarcane genes. However, genomic DNA-based systems are also required because (i) many important genes expressed at low levels are unlikely to be found in libraries and (ii) the cDNA approach provides no information about the crucial on/off switches (promoters, enhancers, transcriptional regulators) that control gene expression. Hence, a comprehensive picture of the sugarcane genome including the entire suite of genes, their all important regulatory elements, and their complete arrangement along the chromosomes will eventually require complete sequencing of the genomes of one or more sugarcane genotypes. Ultimately, this could be achieved with whole-genome sequencing.

A major step toward full genome sequencing would be the construction of large sugarcane bacterial artificial chromosome (BAC) libraries and the generation of detailed genomic maps. Brumbley and Brumbley (2005) generated a library of sugarcane cultivar Q200^A containing 98 000 colonies with an approximate 1 × coverage of the genome. Larger libraries of sugarcane cultivar R570 were constructed at Clemson University and at CIRAD in Montpellier, France. Rapid progress in the speed and cost of DNA sequencing will make feasible the sequencing of entire sugarcane genomes within a few years (Paterson, 2006). Once sequenced, the door is open for candidate gene studies using functional genomics. In the interim, much is likely to be learned from comparative genomics studies using the sequences of closely-related sorghum genome both as a source of control elements and/or as a tool to identify likely candidate genes through comparison of QTLs on sugarcane genetic maps with the physical map of sorghum (Guimarães *et al.*, 1997; Ming *et al.*, 1998).

Sorghum is representative of tropical grasses in that it is classified as a C4 photosynthesizer, comprising complex biochemical and morphological specializations that improve carbon assimilation at high temperatures. By contrast, rice is more

representative of C3 temperate grasses. Sorghum's economic and scientific importance, together with progress in characterizing its genome (detailed below) have motivated the sequencing of an elite inbred line of *S. bicolor* L. genotype, BTx623, to 8x genome coverage under the US Department of Energy Joint Genome Institute (JGI) "Community Sequencing Program" (CSP). Sorghum sequencing was completed in early 2007 and the database is available at the same Harvard University site as sugarcane, <http://compbio.dfci.harvard.edu/tgi/cgi-bin/tgi/gimain.pl?gudb=sorghum>, and annotation is well underway.

The completed sorghum sequence will be an excellent bridge for translating hard-won functional genomics knowledge from *Oryza sativa* L. ssp. *indica* to leading tropical grass crops, with much larger genomes and much more gene duplication. Sorghum and maize diverged from a common ancestor approximately 12 million years ago (Gaut *et al.*, 1997; Swigonova *et al.*, 2004a), versus approximately 42 million years for rice and the maize/sorghum lineage (Paterson *et al.*, 2004). *Saccharum* may have shared ancestry with sorghum as little as 5 million years ago (Sobral *et al.*, 1994) and it retains a similar gene order (Ming *et al.*, 1998), and even produces viable progeny in some intergeneric crosses (Dewet *et al.*, 1976). Maize has undergone a whole-genome duplication since its divergence from sorghum (Swigonova *et al.*, 2004b), and *Saccharum* has undergone at least two (Ming *et al.*, 1998). The low level of gene duplication in sorghum makes it, like rice, an attractive model for functional genomics.

The sorghum sequence will also offer numerous direct opportunities to increase knowledge of sugarcane biology. At the level of genome structure, sorghum and sugarcane chromosomes appear to share very similar gene content and order, and it is expected to be simple to use well-established synteny relationships (Ming *et al.*, 1998), supplemented by a growing body of hybridization marker and end-sequence data to deduce the likely locations in sugarcane of genes identified in the sorghum sequence. Its much closer relationship will make the sorghum sequence of substantially greater value than the rice sequence for such deductions in sugarcane.

A host of classical genetics, supplemented by recent DNA marker studies (Ming *et al.*,

2001a, b, 2002a, b) show heterozygosity resulting from autopolyploidy to be instrumental in the productivity of sugarcane. More generally, genome duplication has long been suggested to play an important role in angiosperm evolution (Stephens, 1951; Ohno, 1970). One of the biggest surprises of the genomics era has been underestimation of the prevalence of ancient whole-genome duplication, finding that even the genomes of diploids such as *Arabidopsis* (Blanc *et al.*, 2000; Initiative, the Arabidopsis Genome, 2000; Paterson *et al.*, 2000; Bowers *et al.*, 2003) and *Oryza* (Paterson *et al.*, 2003, 2004, 2005; Vandepoele *et al.*, 2003; Wang *et al.*, 2005b) have been shaped by genome duplication. Such duplication is associated with a host of rapid responses including loss and restructuring of low-copy DNA sequences (Song *et al.*, 1995; Feldman *et al.*, 1997; Ozkan *et al.*, 2001; Shaked *et al.*, 2001; Kashkush *et al.*, 2002), activation of genes and retrotransposons (O'Neill *et al.*, 1998; Kashkush *et al.*, 2003), gene silencing (Chen and Pikaard, 1997a, b; Comai, 2000; Comai *et al.*, 2000; Lee and Chen, 2001), and organ-specific subfunctionalization of gene expression patterns (Adams *et al.*, 2003, 2004). These mechanisms may be especially important in providing raw material for evolutionary change in sugarcane, in that it appears to have undergone two such genome duplications in about the past 5 million years or so. Sorghum will provide an ideal outgroup for deducing the ancestral states of sugarcane genes that have been affected by genome duplication, in that it is very closely related but diverged prior to the duplication events. Future comparison of the fates of genes in sugarcane to those in *Sorghum halepense*, a polyploid derivative of sorghum, may offer the opportunity to test hypotheses about the degree to which the fates of duplicated genes are determined by a taxon-independent set of molecular principles (Paterson *et al.*, 2006). This could have profound implications for transgenic strategies in the future. For a given trait, are single copies or multiple copies of transgenes more beneficial in sugarcane?

3.2 Expected Products

The future for sugarcane biotechnology is exciting. Because of its narrow genetic base,

there is enormous potential to improve the field performance of this crop. Sugarcane is considered to be an ideal biofactory for the production of a range of sugars, and fine chemicals, including biopolymers, nutraceuticals, industrial enzymes, and pharmaceuticals, for the following reasons: (i) sugarcane is one of the fastest growing and largest biomass-producing agricultural crops in the world; (ii) it accumulates sucrose up to 42% of the dry weight of the stalk. In addition, bagasse (fibrous residue of sugarcane stalks left after extracting the sucrose) is made up of 32–48% cellulose, 19–24% hemicellulose, and 23–32% lignin, all of which all have commercial uses; (iii) it is grown throughout the tropical and subtropical latitudes and is a major crop in many developing nations and can, therefore, be used to help developing economies; (iv) it is usually vegetatively propagated and only produces fertile seed under a specific set of environmental conditions, therefore posing a low risk for transgene flow into the environment; (v) sugarcane crop-cycles run for 4 or more years between plantings. Hence, it does not have to be replanted every year, as it produces new tillers from the stool left in the ground after harvesting; (vi) sugar industries throughout the world already have substantial infrastructure to harvest the large biomass and transport it to mills for processing; and (vii) the tops and leaves of sugarcane, which are traditionally burnt or left behind in the field as a trash blanket, could potentially be used as a production platform for high value biofactory products, as another source of biomass for biorefineries or, more likely, both. In the future, it is highly likely that transgenic sugarcane will be grown not only for the production of sugars for human consumption, but also as a high biomass crop for fuel and energy production, with value adding by metabolically engineering it to produce a range of additional products *in planta*.

3.2.1 Improved sugar

Sugarcane is unusual amongst plants in storing up to 62% dry weight (and 16–25% fresh weight) of sucrose as the primary source of carbon and energy reserve in the storage parenchyma of the mature culm or stalk (Bull and Glasziou, 1963). These are approximate levels obtained in *S. officinarum*, the

major source of commercial hybrid germplasm. In contrast, some of the wild relatives of sugarcane store less than 2% of the fresh weight as sucrose. As the photosynthetic rates on an area basis of *S. spontaneum* have been reported as nearly twice those of *S. officinarum* and 30% greater than that of hybrid cultivars (Irvine, 1975), these striking differences in sink accumulation and storage activity cannot be explained by differences in photosynthetic rates in the leaves (Moore, 2005). Despite many years of research, the process of sugar accumulation is not fully understood.

As more than 70% of the sugar harvested for human consumption is derived from sugarcane (FAO, 2006), improving sugar content in sugarcane will remain as an important focus for future biotechnological innovations. Traditional breeding has improved the yield of sucrose mostly through increased cane yield. Increasing sucrose concentration has not occurred recently through traditional breeding in countries such as Australia, where the levels are already relatively high (Jackson, 2005). Attempts to increase sucrose content in sugarcane cultivars through the modification of plant genes involved in sugar metabolism have been mostly unsuccessful (reviewed by Lakshmanan *et al.*, 2005). For example, a 70% reduction in activity of acid invertase, a key enzyme involved in sucrose breakdown, resulted in no significant change in sucrose yield or purity in the immature internodes of transgenic sugarcane (Botha *et al.*, 2001). A better understanding of sugar-transport pathways will be required for strategies to increase the flux of sugars and, ultimately the amount of sucrose in the storage tissue (Grof and Campbell, 2001; Rae *et al.*, 2005).

The doubled sugar content observed in transgenic sugarcane while attempting to produce isomaltulose (Wu and Birch, 2007) indicates that there is potential to improve sugar content in sugarcane through metabolic engineering of the vacuolar compartment. However, most vacuolar-targeting studies in many crops involving stable transformants have been limited by difficulties in detecting vacuolar-targeted enzyme activities (Ebskamp *et al.*, 1994; van der Meer *et al.*, 1994; Caimi *et al.*, 1996; Ma *et al.*, 2000; Gnanasambandam and Birch, 2004), indicating that the stability of targeted proteins is an important factor for effective metabolic engineering. For isomaltulose

production in sugarcane, a highly efficient sucrose isomerase had to be used (Wu and Birch, 2007).

Reports of experimental efforts to protect foreign gene products from vacuolar degradation are scarce. To understand how to genetically engineer a protein for stability in the vacuole, the “enemies” within the vacuoles—the proteolytic enzymes and their sites of action—need to be characterized (<http://www.proweb.org/other.html>). A method to isolate protoplasts from sugarcane mature stem parenchyma cells has been reported (Gnanasambandam and Birch, 2006), but further optimization is needed for successful vacuole isolation for characterization of proteolytic enzymes. Alternatively, if vacuole isolation proves to be difficult, fluorescent substrates for proteases (from Molecular Probes, Inc.) can be used with isolated protoplasts. Such characterization on proteolytic enzymes may allow for informed modification on foreign proteins to remove sites for attack by sugarcane proteases. Alternatively, directed evolution can be applied to rapidly evolve enzymes for optimal activity under vacuolar conditions (Stemmer, 1994a, b; Chica *et al.*, 2005; Kaur and Sharma, 2006). There may be particular sequences within a protein that are sensitive to proteolytic enzymes, and altering these sensitive sequences may increase protein stability. For example, mutation of protease-sensitive regions of the firefly *luc* yielded larger and more stable signals compared with the wild-type protein in *E. coli* (Thompson *et al.*, 1997).

3.2.2 Alternative or novel sugars

There have already been examples of alternative sugars produced in genetically modified (GM) sugarcane (Section 2). In addition to isomaltulose (Wu and Birch, 2007) and sorbitol (Chong *et al.*, 2007), there is potential to engineer synthesis of a range of other sugar complexes and sugars into sugarcane, for example alternative carbohydrates such as starch and fructans (already demonstrated in sugarbeet).

Tagatose (Kim, 2004) has properties closer to sucrose than any of the other sugar substitutes. D-Tagatose is an isomer of D-galactose and it can function as a low-Joule sweetener. Although

it has relatively the same sweetness as sucrose, it is detected on the tongue sooner.

Xylitol is a sugar alcohol of considerable commercial interest (Granström *et al.*, 2007a, b). Its metabolism in humans is independent of insulin and it is anticariogenic. It also has uses as a pharmaceutical. Xylose is a major component of sugarcane hemicellulose, making up 25% of the w/w dry matter and 91% of the nonfermentable sugars (Pessoa Jr. *et al.*, 1997). Research is currently underway to optimize the conversion xylose to xylitol. *Candida guilliermondii* has been used as a test species on sugarcane bagasse hydrolysate, because it naturally metabolizes xylose (da Silva and Felipe, 2006). However, *Candida* cannot be used in food production, because many *Candida* species are pathogens. An alternative is to use bacteria. When a xylose reductase and a xylose transporter were engineered into the bacterium *Lactococcus lactis*, levels of xylitol production were equivalent to those in the best-producing *Candida* line (Nyyssölö *et al.*, 2005). An alternative would be to engineer a xylose reductase into sugarcane. One strategy might be to have the enzyme incorporated into the sugarcane cell wall structure, so that it is only functional when it is released during sugarcane processing at the mill. Another might be to regulate it with a wound-inducible promoter, so that it is produced in the sugarcane cells after harvesting. In both of these scenarios, the enzyme(s) will have to be engineered to function at the temperatures and pH of a sugar mill and in particular under mill conditions designed to break down hemicellulose (Pessoa Jr. *et al.*, 1997).

Though there has been much research toward the development of low-Joule nonsucrose sweeteners (Modi and Borges, 2005), two such sweeteners (saccharin and cyclamates) were found to be carcinogenic under some circumstances, while others (such as aspartame) exhibit temperature and low pH instability that limit their utility (Knight, 1994). Hence, it may be useful to produce a low-Joule nonsucrose product from sugarcane. Alternatively, there are a range of sweet proteins that may be worth considering. Monellin, Thaumatin, and Brazzein are 100 000, 3000, and 500 times sweeter than sucrose, respectively. These would be a natural replacement for synthetic sugars because they are low-Joule sweeteners and would not trigger insulin production (Kant, 2005).

3.2.3 The biorefinery—biofuels and biochemicals

Sugarcane is expected to become a platform for biorefinery production of fuels and chemicals. Recent demand for renewable energy sources has increased the interest within the research community on transgenic breeding for biomass production. Sugarcane is the crop having the most favorable input/output balance for bioenergy, and with the growing body of research on its genome, may allow the development of a low-input energy crop with key outputs as biofuel (ethanol) and bioenergy (electricity). The production of an alternative energy crop, with high biomass potential, will be a significant step toward the implementation of a biofuels, bioenergy, and, in the not too distant future, bioproducts industries. If biorefineries, producing dozens of products (Figure 6) are integrated into sugar mills, one can envision a sugarcane industry functioning more like petrochemical plants do today. Unlike petrochemical plants, the resource driving this new bioeconomic revolution will be renewable.

In nature, the most prevalent forms of carbon are the biopolymers cellulose and hemicellulose (Houghton *et al.*, 2006). The third most abundant biopolymer is lignin (van Dam *et al.*, 2005). These are considered to be the raw materials for future bio-based industries creating opportunities for sugarcane industries to diversify. Aside from water, sugarcane plants are primarily comprised of cellulose, hemicellulose, and lignin. Traditionally, this resource has been combusted, either in the field to remove the leaf material or at the mill to utilize the waste product bagasse to generate the necessary energy to power mill operations. Since the mid-1980s, it has been proposed that “energy cane” should be introduced as a multiple product alternative to sugarcane grown largely for sucrose (Alexander, 1984, 1985). The time may have come to implement this vision with the inclusion of advances in the fields of biotechnology. Changing the sugarcane industry from primarily a one-product to a multiple-product industry is an enormous challenge, but there are multiple indicators that should make both sugarcane farmers and millers optimistic.

Of all the agricultural crops, sugarcane may be the most ideally suited to benefit from a shift to a bio-based economy because of its large biomass

and, therefore, large quantities of cellulosic and hemicellulosic sugars and lignin (Alexander, 1984, 1985; Brumbley *et al.*, 2004, 2006b, c, 2007). There is good reason for simultaneously developing sugarcane both as a biofactory and as a feedstock for biorefinery processes. As technologies are developed to produce a range of new and diverse products in the sugarcane plant, other technologies are being developed to dismantle the cellulose and hemicellulose to release the large quantities of fermentable sugars from biomass. The breakdown of the tough structural elements that make up sugarcane cell walls will facilitate the extraction of new bioproducts such as the bioplastics described in Section 2.

The biofuel ethanol is becoming increasingly more important as the world attempts to wean itself off its addiction to petroleum-based fuels. The second largest producer of ethanol in the world is Brazil, and sugarcane is their feedstock (Pessoa Jr. *et al.*, 2005; Lorentzen, 2006). In the near future, another bio-based fuel (butanol) may enter the market. DuPont and British Petroleum recently formed a joint venture to produce this biofuel commercially. Butanol resolves many of the problems of ethanol. Not only does it have a higher energy content, it is not as corrosive, uses an air/fuel ratio that is closer to that of gasoline, can be shipped through existing fuel pipelines, is safer to handle, and can replace gasoline at any percentage up to 100%.

Governments and private industry are investing in technologies to convert biomass into biofuels and biochemicals. Cellulose, hemicellulose and lignin interact to form plant cell walls and are responsible for giving plants their structural integrity. Compared to starch, getting to the sugars that make up these polymers is far more difficult and more expensive (Bayer *et al.*, 2004; Houghton *et al.*, 2006). A diverse range of bacteria have been discovered that have multienzyme complexes that bind to and degrade cellulose and hemicellulose. This complex has been termed the cellulosome and the research on these enzyme complexes was reviewed recently (Bayer *et al.*, 2004). Researchers are looking for new organisms with cellulose degrading capabilities. Once discovered, activity and performance of these enzymes and complexes can be improved using directed evolution (Joyce, 2004; Neylon, 2004; Hibbert and Dalby, 2005).

Figure 6 Potential product targets for sugarcane-based biofactories and biorefineries. From just a few building blocks an array of secondary and intermediates chemicals can be produced. The intermediate chemicals are the building blocks of a vast range of end product. [Reproduced with permission from Todd Werpy and Gene Petersen, the lead authors of “Top Value Added Chemicals from Biomass”]

The pool of sugars currently locked up in cellulosic biomass could be used to feed biorefineries both for the production of biofuels and bioproducts. White biotechnology (Paster *et al.*, 2003) is the use of biological processes for the production of chemicals such as plastics, adhesives, and paints. Fermentation technologies could be used to produce building block chemicals that will be the basis for the range of secondary and intermediate chemicals (Figure 6). Currently, the United States and European Union annually produce €1000 billion worth of fine and bulk chemicals from a petroleum feedstock. They plan to shift over 90% of this production from a petroleum to a biorenewable base over the next 50 years. To accomplish this, new enzymes will be required to convert the sugars within the cellulosic biomass to the renewable building blocks required by tomorrow's manufacturing sector.

The vast majority of microbes have never been characterized. This enormous and diverse population is thought to be a rich source of new genes, metabolic pathways, and enzymes. However, most of these organisms are not culturable. Metagenomics is the study of the collective genomes of organisms, independent of growth in culture. The tools for doing metagenomics are advancing rapidly (Tringe and Rubin, 2005; Green and Keller, 2006). For example, Venter *et al.* (2004) used metagenomics to identify over 1.2 million new genes from at least 1800 species, including 148 previously unknown bacterial groups, just in the Sargasso Sea. As our understanding of protein domains advances (Portugaly *et al.*, 2007), it may be possible to design "lab-on-a-chip" devices (Hong *et al.*, 2004) that can be used to rapidly screen different environmental samples for genes encoding specific enzyme domains. Using systems biotechnology, newly discovered enzyme's can be characterized rapidly and their utilities for industrial bioprocessing determined (Lee *et al.*, 2005). Directed evolution tools, such as domain shuffling (Hibbert and Dalby, 2005), can be utilized to combine the new enzyme's functional domains with those of other related enzymes to create an enzyme that will function in the precise environment it is needed, whether that is a fermentation tank inside the cytoplasm, storage vacuole, mitochondria, peroxisome, or plastid of a sugarcane cell.

3.2.4 Biopolymers

A potential major industrial use for sugarcane is the production of biodegradable polymers. These polymers can be produced by fermentation technologies and, as shown in Section 2, can be produced in sugarcane. For example, PHAs are polyesters synthesized naturally by many species of bacteria as carbon sources and energy reserves. PHAs are accumulated to levels as high as 90% of the cell dry weight in bacteria. PHAs have the properties of thermoplastics and elastomers and they are biodegradable (Madison and Huisman, 1999). These classes of biopolymers offer a renewable and environmentally friendly alternative to the 150 t per year of plastic currently produced from petrochemical resources.

In nature, over 130 PHA variations have been identified that produce plastics with properties varying from hard and brittle, too elastomeric, glue-like, and even rubbery (Steinbüchel and Valentin, 1995). PHAs are classified based both on the length of the side chains on the polymer (i.e., whether the side chains are short (C4-6) or medium (C6-16) in length), and on whether the polymer is a homopolymer, or a co-polymer of PHAs with different side chains. In the case of co-polymers, the ratio of medium (mcl) to short side (scl) chains also affects the properties. Co-polymer PHAs of commercial interest range from 2% mcl (hard, brittle) to 20% mcl (soft, elastic). PHB, the most studied of the PHAs, is a short-side-chain homopolymer and displays properties similar to polypropylene (Hocking and Marchessault, 1994).

In Brazil, an important precedent has been established on how to diversify the product base of a sugar industry, first with ethanol, and then with bioplastics (Lorentzen, 2006; Velho and Velho, 2006). In 1992, initial projects were funded to develop a novel platform for the production of PHB from sugarcane through fermentation (Velho and Velho, 2006). The Brazilian company Copersucar (<http://www.copersucar.com.br>) first engineered the bacterium *Ralstonia eutropha* to use sucrose as a carbon source. A pilot plant was then built, integrated into a sugarcane mill (<http://www.biocycle.com.br>), and ultimately produced 50 t per year of high purity PHB. This refinery receives its feedstock (sugar syrup) directly from the sugar mill, which also produces all of the energy necessary to run the fermentation,

extraction, and purification facilities. The solvents for PHB extraction are also sugar mill products sourced from the ethanol production facility (Velho and Velho, 2006). This model is an excellent example of how an existing resource industry can, with government and corporate support, build on its knowledge base to create new business opportunities and a help establish bio-based economy in a developing country (Lorentzen, 2006).

BiopolTM (Choi and Lee, 1999) is the only PHA co-polymer that has been produced commercially. However, Metabolix, Inc. has formed a strategic alliance with Archer Daniels Midland (ADM) to commercialize PHA natural polymers. Metabolix and ADM claim that they can make these natural plastics by fermentation at costs that are competitive, or near competitive, with petrochemical-based plastics (<http://www.metabolix.com>). Metabolix argues that producing these plastics in the cells of living plants will reduce this cost even further. Hence, agricultural crops are regarded as a promising low-cost alternative for the production of PHAs on a large scale (Snell and Peoples, 2002). High-level production (approximately 40% of dry weight) of PHB has been achieved in plants by introducing three *R. eutropha* genes encoding a β -ketothiolase (*phaA*), an acetoacetyl-CoA reductase (*phaB*), and a PHA synthase (*phaC*) (Bohmert *et al.*, 2000). The success in the production of PHB in sugarcane (Petrasovits *et al.*, 2007; Purnell *et al.*, 2007) indicates that other biopolymers can be produced in sugarcane.

3.2.5 Natural products/pharmaceuticals/proteins

There are opportunities to engineer the metabolism of sugarcane to increase production of natural products (Dixon, 2005). For instance, the most functionally and structurally diverse group of plant metabolites is the isoprenoids (also called terpenoids). These diverse compounds have a commercial value as flavors, pigments, polymers, or drugs (reviewed in Rodríguez-Concepción, 2006; Withers and Keasling, 2007). There are other good reasons to learn how to manipulate and/or regulate isoprenoid production in sugarcane, as they play primary roles in respiration, photosynthesis, and regulation of growth and

development. As secondary metabolites, they function in protecting plants against herbivores and pathogens, attract pollinators and seed dispersing animals, and influence competition among plant species (Rodríguez-Concepción, 2006).

As described in Section 2, some work has already been done to engineer sugarcane to produce pharmaceuticals and high-value and bulk proteins. Monoclonal antibodies (mAbs) are one class of pharmaceutical proteins with considerable potential for production in plants. The estimated market size for mAbs is expected to exceed US \$20 billion per year (Reichert *et al.*, 2005). Both IgG- and IgA-type antibodies have been successfully produced in plants (Giritch *et al.*, 2006). Recently a new transient expression technology, “magniffection”, for production of gram quantities (0.5 g kg^{-1} fresh leaf biomass) of mAbs in plant cells was reported (Giritch *et al.*, 2006). The time from gene delivery to production of fully assembled mAb is 14 days and to production of gram quantities is 14–20 days, making it the fastest production platform available (Hiatt and Pauly, 2006). This system uses vectors from two different noncompeting plant viruses, one for producing the heavy chain and one for the light chain, and transfers them to the plant via *Agrobacterium*-mediated transformation.

One area that may hold promise is the production of industrial enzymes. Future biorefineries are going to require a host of enzymes for converting base material into the raw materials required by the manufacturing sector (Figure 6). Some of the enzymes can be produced directly in the sugarcane cells, and potentially at high concentrations once plastid transformation technologies are developed for sugarcane.

3.2.6 Drought tolerance

In most crops, past breeding efforts for drought tolerance have been hindered by the quantitative genetic basis of the trait and the poor understanding of the physiology (reviewed in Tuberosa and Salvi, 2006). For breeders, it is important to select genotypes that are able to optimize water uptake and water use efficiencies and minimize damage incurred by drought stress.

This ultimately will lead to maximized yields. In an effort to select for improved drought tolerance, breeders have identified a myriad of morphophysiological QTLs acting from the cellular to the whole crop level (reviewed in Tuberosa and Salvi, 2006). However, given the genetic complexity of sugarcane, a marker-assisted selection approach for a myriad of improved drought tolerance QTLs would appear a very difficult proposition. An alternative way forward would be to make use of the knowledge gained in simpler systems and identify candidate genes to test in sugarcane. Candidate genes for drought tolerance have been divided into three broad areas including: (i) functional proteins such as enzymes involved in osmotically active compounds, transporters, chaperones, and reactive oxygen species (ROS) scavengers; (ii) transcription factors involved in the plant response to drought stress; and (iii) signaling factors upstream of transcription factors, including protein kinases and proteins involved in phospholipid metabolism, calcium sensing, and protein degradation (reviewed in Umezawa *et al.*, 2006; Valliyodan and Nguyen, 2006). Most of these validation studies have been undertaken with model plants in laboratory or glasshouse conditions. An important next step is to trial these approaches in crop species under field conditions.

In other plants, a variety of transgenes have been used to improve drought tolerance. Examples include, the barley *HVA1* gene (Fu *et al.*, 2006), manganese superoxide dismutase (Wang *et al.*, 2005c), regulator of G-protein signalling protein (RGS) (Chen *et al.*, 2006), and aldehyde dehydrogenase (Rodrigues *et al.*, 2006). Perhaps the most widely and successfully used genes have been the *CBF/DREB* group of transcription factors (Agarwal *et al.*, 2006). *CBF/DREB* is a class of transcription factors that binds to drought responsive *cis*-acting elements and is important in regulating gene expression in response to drought, high salt, and cold stress (Yamaguchi-Shinozaki and Shinozaki, 1994). The ability of *CBF* to enhance tolerance to cold stress (Jaglo-Ottosen *et al.*, 1998) and drought stress (Haake *et al.*, 2002) was first demonstrated in *Arabidopsis* and has subsequently been shown to enhance tolerance to abiotic stress in commercially important crops such as tomato (Hsieh *et al.*, 2002; Lee *et al.*, 2003b) and rice (Ito *et al.*, 2006).

Sugarcane lines have been produced containing a gene encoding drought-induced *Arabidopsis* transcription factor, *AtCBF4* (McQualter and Dookun, 2007). Under glasshouse conditions, plants containing *AtCBF4* driven by the constitutive maize polyubiquitin promoter showed growth retardation. Research is now focused on using drought-inducible promoters to reduce this negative phenotype.

As mentioned in Section 2, trehalose has already been used to engineer drought tolerance in sugarcane (Zhang *et al.*, 2006). There are also a number of other potential osmoprotectants that can be trialed in sugarcane. These include betaines, the amino acids proline and ectoine, and polyols mannitol and sorbitol (Rontein *et al.*, 2002). As mentioned above, transgenic sugarcane plants have been generated that produce sorbitol (Chong *et al.*, 2007) and are being progressed to field trials.

3.2.7 Disease and insect resistance

Estimates of the cost of control and loss due to major sugarcane pests and diseases in Australia are in the order of 10% of the total value of the sugarcane crop (McLeod *et al.*, 1999). Of these diseases and pests, soil-borne pathogens caused an estimated 75% of the losses, followed by canegrubs (larvae of Scarabaeidae) (10%), ratoon stunting disease (caused by *Lxx.*) (6%), and brown rust (caused by *Puccinia melanocephala* H&P Sydow) (3%). Occasionally, disease outbreaks due to the breakdown of disease resistance occur, which can result in much larger losses (40% reduction in cane yield in some sugarcane growing regions in Australia as a result of orange rust (Magarey *et al.*, 2001)). Diseases such as ratoon stunting disease, pineapple disease, and red rot can be largely controlled by farm hygiene processes such as sterilizing cutting and harvesting equipment and by the use of fungicides (Magarey, 2005). However, for most sugarcane diseases, genetic resistance is the most effective method of disease management and sugarcane breeders have done an excellent job in controlling diseases through the use of resistant cultivars.

In the future, it is possible that resistance may break down, and aside from introgressing wild germplasm with novel resistance (if this exists in the gene pool), alternative strategies will be

needed. Such approaches should provide durable resistance, preferably against a range of pathogens. Genetic engineering has the potential to achieve this through inserting carefully selected and possibly multiple genes as transgenes that (i) confer durable broad-spectrum resistance; (ii) are safe for all other organisms; and (iii) cause no yield penalty in the plant (Gurr and Rushton, 2005a). Such approaches have been successful with chewing insect pests, where expression of an insecticidal protein from *B. thuringiensis* has lead to increased yields and reductions in insecticide applications in cotton, soybean and maize (reviewed Gurr and Rushton, 2005b). Recent work in transgenic sugarcane has also indicated that *Bt* proteins are active against stem borers (Weng *et al.*, 2006). Strategies for resistance to sugarcane viruses have also met with some success through RNAi-mediated approaches against the single-stranded RNA SCMV and the double-stranded RNA FDV (Joyce *et al.*, 1997; Ingelbrecht *et al.*, 1999; McQualter *et al.*, 2004). However, similar successes for durable resistance to bacteria and fungi have not been forthcoming (reviewed Gurr and Rushton, 2005a).

Strategies have attempted to boost disease resistance through constitutive overexpression of defense components or single-antimicrobial proteins and have led to a variety of problems including poor quality plants, yield reduction, poor efficacy, or short durability (reviewed by Gurr and Rushton, 2005b). New strategies are being explored to overcome these problems. For example, a two-component system has been suggested, where the manipulation of “master switch” genes (such as kinases and transcription factors), which regulate entire signaling pathways are coupled with pathogen-inducible promoters to precisely regulate spatial and temporal gene expression (Yamamizo *et al.*, 2006). Other strategies have come from the genomics field, for instance the complete genome of *Lxx*, has been fully sequenced (Monteiro-Vitorello *et al.*, 2004) and opportunities now exist to try and control or even eradicate this costly pathogen from sugarcane (Brumbley *et al.*, 2006a). Global transcriptional analysis of plant pathogen interactions has also revealed pivotal steps in defense responses that may be targeted in future strategies (Zabala *et al.*, 2006). Further disease control strategies may involve pyramiding two or more antimicrobial

proteins to improve efficacy and durability of resistance.

Work on transcription factors in other plants may offer some future promise for sugarcane. WRKY proteins are a large family of transcription factors that mainly participate in plant biotic-stress responses (Liu *et al.*, 2007). They share a DNA-binding domain consisting of about 60 amino acids, as well as additional conserved features that distinguish individual subgroups (Eulgem *et al.*, 2000). WRKY transcription factors can bind to domains in the promoters of pathogen-response genes, termed W boxes (TTGACC) (Maeo *et al.*, 2001; Turck *et al.*, 2004). While overexpression of some WRKY transcription factors has resulted in enhanced resistance to various bacterial or fungal pathogens, others can suppress the expression of defense-related genes.

Chen and Chen (2002) transformed *Arabidopsis* plants with AtWRKY18 under control of the CaMV 35S promoter. Transgenic AtWRKY18 plants showed marked increase in the expression of pathogenesis-related genes and resistance to the bacterial pathogen *Pseudomonas syringae*. Thus, AtWRKY18 was shown to positively modulate defense-related gene expression and disease resistance. Conversely, AtWRKY7 transcription factor plays a negative role in defense responses to *P. syringae*. Kim *et al.* (2006) studied the biological function of the *Arabidopsis* WRKY7 gene in both loss-of-function T-DNA insertion and RNAi mutants and gain-of-function transgenic overexpression plants. The T-DNA insertion and RNAi mutant plants displayed enhanced resistance to a virulent strain of the bacterial pathogen *P. syringae*. Transgenic *Arabidopsis* plants that constitutively overexpress WRKY7 showed reduced expression of defense-related genes, including *PR1* and developed more severe disease symptoms than wild-type plants.

A large number of WRKY genes have also been identified in rice. Ryu *et al.* (2006) isolated WRKY transcription factors whose expressions were altered upon attack of the fungal pathogen *Magnaporthe grisea*, the causal agent of rice blast disease. Among 45 tested genes, the expression of 15 was increased in interactions between rice and *M. grisea*. Twelve of this subset of genes were also differentially regulated in rice plants infected with the bacterial pathogen *X. oryzae* pv. *oryzae* (X.o.o) 13751. Ryu *et al.* (2006) suggested that a

large number of *WRKY* DNA-binding proteins are involved in the transcriptional activation of defense-related genes in response to rice pathogens. Several pathogenesis-related genes were induced in *OsWRKY03*-overexpressing transgenic rice plants (Liu *et al.*, 2005), while overexpression of the *OsWRKY71* gene in rice resulted in enhanced resistance to virulent bacterial pathogen X.o.o. 13751 (Liu *et al.*, 2007).

As mentioned above, there are extensive databases at Harvard University covering plants, animals, fungi, and protists. The TIGR has the Comprehensive Microbial Resource (CMR) (<http://cmr.tigr.org/>). Within this free database are the complete genome sequences of 354 bacteria, including a number of plant pathogens. There is currently an effort to reduce the cost of sequencing the genome of a bacterium to under US \$1000, and this is likely to be accomplished in the next decade. When that happens, databases such as the one at TIGR and Harvard University will contain the genomes of the vast majority of plant pathogenic bacterium, fungi, viruses, and mycoplasmas as well as the insect pests that plague agriculture around the world. Studying the plant-microbe or plant-insect interaction in the future will be done at the whole genome, transcriptome, proteome, and metabolome level of the host, and the pests and pathogens.

3.2.8 Modified plant architecture and development

Shoot architecture describes the way in which the aerial portions of plants develop. It is influenced predominantly by shoot branching and plant height. Agronomic interest in shoot architecture has stemmed mainly from potential yield increases associated with some plant ideotypes. For instance, height reduction in cereals has led to yield improvement through decreased lodging, whilst reduction of tillering in some cereals may lead to yield improvements (Duggan *et al.*, 2005).

In sugarcane, complex interrelationships exist among shoot architecture, stalk characteristics, cane yield, and sucrose content (Milligan *et al.*, 1990). For instance, two elements of sugarcane shoot architecture, the number and weight of stalks, determine cane yield. However, stalk number and stalk weight are negatively correlated

and, thus, selecting for either trait alone may not result in increased cane yield (Milligan *et al.*, 1990; Bell *et al.*, 2004; Bell and Garside, 2005). Stalk architecture can also affect cane sucrose content. Taller canes are more likely to lodge under wet or windy conditions, causing a reduction in sucrose content (Singh *et al.*, 2000, 2002), whilst clones with a propensity for producing the low-sugar-content suckers reduce the sucrose content of the harvested crop (Bonnett *et al.*, 2001, 2004a).

Recently, several genes controlling shoot architecture traits, such as stalk height and tillering, have been described (McSteen and Leyser, 2005; Wang and Li, 2006). There is now an opportunity to test how modifying stalk characteristics with these genes will affect cane yield and sucrose content in the same sugarcane cultivar without altering other genes in the plant. Three areas of research have been identified which may lead to increased yields, accelerated biomass production, controlling lodging, and reducing suckering. The genes that are currently being used to address these research areas are the *TB1* gene, which has been shown to affect tiller number and stem width in maize and rice (Doebly *et al.*, 1997; Takeda *et al.*, 2003), the *MAX3* gene that affects axillary meristem outgrowth in rice (Zou *et al.*, 2006) and *Arabidopsis* (Booker *et al.*, 2004), and several gibberellin oxidases that regulate stem elongation (Hedden and Phillips, 2000). Transgenic sugarcane plants have been produced and are currently undergoing extensive glasshouse and field trials to test what effects these genes produce (Pribil *et al.*, 2007).

3.2.9 Other products

3.2.9.1 Products from phenylpropanoid pathway

The phenylpropanoid pathway is an important plant-metabolic pathway involved in the synthesis of defense-related secondary metabolites and in the production of structural-reinforcement polymers, including lignin (Matsuda *et al.*, 2005). The phenylpropanoid pathway produces a large and diverse array of chemicals, both as intermediates and as end products. Enzyme levels in the phenylpropanoid pathway are tightly regulated (Ni *et al.*, 1996) and flux into the phenylpropanoid pathway is controlled, at least

in part, via feedback regulation of PAL, sensed through production of cinnamic acid (Blount *et al.*, 2000). PAL is regulated both transcriptionally and post-transcriptionally (Dixon and Paiva, 1995). This is an important consideration when attempting to over-produce intermediates or end products of the phenylpropanoid pathway by attempting to increase flux through the pathway.

The MYB and bHLH group of transcription factors are involved in regulation of the phenylpropanoid, anthocyanin, and flavonoid pathways. Various branches of phenylpropanoid metabolism are regulated by branch-specific activating and repressing MYB transcription factors, sometimes dependent on bHLH (Vom Endt *et al.*, 2002). MYB transcription factors have been identified, which regulate the first steps in the phenylpropanoid pathway.

Maeda *et al.* (2005) isolated carrot cDNA encoding the R2R3 type of MYB transcription factor (*DcMYB1*) and found that transient expression of *DcMYB1* could up-regulate the PAL gene (*DcPAL1*) promoter activity in carrot protoplasts. Induction of *DcPAL1* expression occurred 1 h after *DcMYB1* expression in carrot protoplasts under various stress treatments, including treatment with a fungal elicitor and by ultraviolet-B (UV-B) irradiation. When *DcMYB1* expression was repressed using RNA interference, up-regulation of *DcPAL1* expression was negated. It was suggested that *DcMYB1* is the main regulatory factor of the *DcPAL1* gene that responds to environmental cues.

Jin *et al.* (2000) produced an *Arabidopsis* line that was a mutant of the R2R3 MYB gene, *AtMYB4*, which showed enhanced levels of sinapate esters in its leaves. The mutant line was more tolerant of UV-B irradiation than the wild type. The increase in sinapate ester accumulation in the mutant was associated with an enhanced expression of the gene encoding cinnamate 4-hydroxylase (C4H), which appears to be the principal target of *AtMYB4* and an effective rate limiting step in the synthesis of phenylpropanoids. *AtMYB4* works as a repressor of target gene expression and includes a repression domain. It belongs to a novel group of plant R2R3 MYB proteins involved in transcriptional silencing (Jin *et al.*, 2000).

The ability to significantly modify flux through the phenylpropanoid pathway would be beneficial

for research targeted at producing novel compounds in sugarcane. McQualter *et al.* (2005) evaluated sugarcane as a production platform for p-hydroxybenzoic acid using 4-hydroxycinnamoyl-CoA hydratase/lyase (HCHL) from *P. fluorescens* (Gasson *et al.*, 1998) that provides a one-enzyme pathway from a naturally occurring plant intermediate (Mayer *et al.*, 2001). The substrate for HCHL is 4-hydroxycinnamoyl-CoA (a cytosolic phenylpropanoid intermediate). HCHL elevates p-hydroxybenzoic acid levels in plants (Mayer *et al.*, 2001), and its expression in transgenic sugarcane led to the accumulation of p-hydroxybenzoic acid glucosyl conjugates to as high as 7.3% and 1.5% DW in leaf and stem tissue, respectively, with no discernible phenotypic abnormalities (McQualter *et al.*, 2005). However, as a result of diverting carbon away from the phenylpropanoid pathway, there was a severe reduction in leaf chlorogenic acid, subtle changes in lignin composition, as revealed by phloroglucinol staining, and an apparent compensatory up-regulation of PAL. Product accumulation in the leaves at the highest level of gene expression obtained in the study was clearly substrate limited. Increasing flux through the phenylpropanoid pathway in sugarcane by increasing the expression of the *PAL* gene (the first enzyme in the phenylpropanoid pathway) using a sugarcane ortholog of *DcMYB1* could help overcome substrate limitation problems and enable economically viable amounts of p-hydroxybenzoic acid to be produced in transgenic sugarcane. Additionally, silencing the repressor function of a sugarcane ortholog of the *AtMYB4* transcription factor could increase flux through the pathway at the C4H rate-limiting step (the second step in the phenylpropanoid pathway).

3.2.9.2 Flavonoids

Flavonoids form a large group of polyphenolic compounds produced in plants that encompass the wide variety of phytochemicals present in the human diet. Basic research, animal model, and human studies suggest flavonoid intake may reduce the risk of several age-related chronic diseases (Graf *et al.*, 2005). Duarte-Almeida *et al.* (2006) identified phenolic compounds in sugarcane (*S. officinarum*) juice showing the predominance of flavones (apigenin, luteolin,

and tricin derivatives) among flavonoids, and of hydroxycinnamic, caffeic, and sinapic acids, among phenolic acids, representing a total content of around 160 mg l⁻¹. A tricin derivative was present in the highest proportion (>10% of the total). The phenolic extract obtained from sugarcane juice showed a protective effect against *in vivo* MeHgCl intoxication and potent inhibition of *ex vivo* lipoperoxidation of rat brain homogenates, indicating a potential use for beneficial health effects and/or therapeutic applications.

A transgenic approach to enhancing flavonol content in sugarcane has not yet been attempted. However, the maize transcription factor genes *LC* and *CI* have been expressed in transgenic tomatoes, resulting in increased flavonoid levels (Bovy *et al.*, 2002). Tomato fruit normally contain small amounts of flavonoids in the peel, but co-expression of the *LC* and *CI* genes enabled up-regulation of the flavonoid pathway in the flesh of the tomato fruit, a tissue that does not normally produce flavonoids. This resulted in a strong accumulation of flavonols and a modest increase in flavanones.

3.3 Economic Opportunities, Industrial Perspectives, and Political and Economic Consequences

Around the world a paradigm shift is being forced by the concern that we have reached the end of the age of inexpensive crude oil. This is being caused by a shortage of crude oil brought on by (i) the rapid industrial development of China and India (Goodstein, 2004); (ii) the political instability in the major crude oil producing regions of the world; and (iii) the fact that we are either at or very close to the peak for world oil production/reserves (Hubbert, 1956). The process of weaning the world off crude oil has begun, and the transition from a petroleum-based economy to a bio-based economy is underway. Nowhere is this more apparent than in the legislation being enacted in the European Union (EU). Manufacturers in the global automotive, packaging, electronics, and chemical industries will be responsible for the end-of-life processing of their products sold or produced in the EU. This means it will become increasingly more expensive to dispose of

manufactured goods, forcing companies to recycle or reuse (End-of-Life). For instance, 100% of all electronics, most parts of automobiles, and all the packaging sold in the EU will have to be reusable or recyclable.

Clear “Vision Statements” and “Roadmaps” of the EU and the US R&D funding bodies are now in place (Europa, Plants for the future; EPOBIO; [http://www.suschem.org/content.php?_document\[ID\]=2049&pageId=2491](http://www.suschem.org/content.php?_document[ID]=2049&pageId=2491); United States Department of Energy Genomics, GTL roadmap; <http://www.eere.energy.gov/biomass/publications.html#vision>). The corporate world is also investing heavily with the largest focus on biofuels. Biorefineries are being constructed worldwide, primarily to produce ethanol. Additional investments are being made in the production of fine chemicals using fermentation technologies. The production of diverse biopolymers is an area with considerable attention. Examples include: (i) Cargill’s Natureworks, bioplastics made from polylactic acid; (ii) Dupont’s Sorona™ (http://www2.dupont.com/Sorona/en_US), the major component, 1,3-propanediol, is being produced in a joint venture with Tate & Lyle; and (iii) Metabolix’s Natural Plastics based on PHA, which will be produced in a joint venture with Archer Daniels Midland (<http://www.metabolix.com/index.html>). All of these polymers begin with the simple sugars found in corn starch.

What does all this have to do with transgenic sugarcane? The Visions and Roadmaps from the EU and US, the investment in R&D by governments around the world, and by corporations in new bio-based businesses can only mean opportunity (European Union Framework Seven, United States Farm Bill, DuPont, Toyota, Cargill, Abengoa). To make sugarcane attractive for investment, such as is happening in Brazil, the technologies to engineer sugarcane must be advanced. In the future, sugarcane could be genetically engineered to grow more sugar and biomass per hectare, use less water and fertilizer, be resistant to a range of pests and diseases, produce its own bioherbicide to out-compete weeds, be able to grow on marginal land, and be able to grow in drier and cooler climates. The process of harvesting sugarcane could trigger a cascade of enzymes that would start degrading the chains of sugars that make up cellulose and hemicellulose, and modify the lignin, making the sugarcane easier

to mill. This would help produce a larger pool of sugars readily accessible for the biorefineries linked to the sugarcane mills. Sugarcane could also be engineered so that a range of products other than sugars could be produced in its cells while it is growing in the field, adding additional value and further diversifying its product base.

Much of the basic research to accomplish this is already underway. The core lesson from Brazil is that it takes years or even decades to develop the knowledge base, the core skills, and the infrastructure for a bio-based economy (Lorentzen, 2006; Velho and Velho, 2006). The economic prosperity that Brazil is now enjoying because of sugarcane and its byproducts has taken them almost 40 years to develop. This prosperity gives them both the money to invest and a desire to continue this growth cycle. This creates opportunities to commercialize GM sugarcane with improved properties.

The most advanced programs for commercial release of transgenic sugarcane are in Brazil, South Africa, USA, India, China, The Philippines, and Australia. The Centro de Tecnologia Canavieira (<http://www.ctc.com.br>) recently announced it would be field-testing three new transgenic sugarcane varieties with 15% increase in sugar yields (<http://www.inovacao.unicamp.br/english/report/news-sugaralcohol060522.shtml>).

The economic prosperity of the Brazilian sugarcane industry is also being mirrored in the US maize industry. The growing global bioeconomy provides opportunity for any industry that is willing to invest in the infrastructure to produce large quantities of inexpensive sugars. Sugarcane industries are particularly well suited because they already have in place the mechanism to haul very large quantities of biomass from where it is grown to where it is processed. The sugars locked up in this biomass have the interest of governments and industries alike. Many believe that the sugars in the cellulose and hemicellulosic biomass are the replacement for crude oil. The United States and the EU see the tools of the biotechnology revolution as fundamental to this process.

Biology and engineering are merging at the computer interface through the fields of genomics (Sanford *et al.*, 2002; Morgante, 2006), transcriptomics, proteomics (Heazlewood and Millar, 2003), metabolomics (Oksman-Caldentey and Saito, 2005; Rockfort, 2005), and fluxomics

(Sanford *et al.*, 2002), generating enormous data sets that are allowing for the development of systems biology (Lee *et al.*, 2005; Barrett *et al.*, 2006; Joyce and Palsson, 2006). Using these databases, experiments are designed and tested on a computer before being trialed in a laboratory (Lee *et al.*, 2005). One person working in the corner of one laboratory can accomplish more in a few months than was previously accomplished by research teams working throughout their entire careers. These powerful tools could not have come at a better time, as the rising demand for crude oil starts to impact on price, which potentially could play havoc with the world's economies (Goodstein, 2004).

3.3.1 Human health and environment

There is no reason to assume that genetic engineering has a greater potential to harm human health or the environment than any techniques used in classical breeding (Miller, 2007). If there is a lesson we have learned from the enormous experience of commercially growing GM crops on over 1 billion acres (400 million hectares) around the world for over two decades is that if the trait(s) encoded by the transgenes are safe, then there are more than sufficient safeguards in traditional breeding programs to ensure that the GM-derived crop is safe (Bradford *et al.*, 2005).

However, there is still considerable resistance to food derived from GM plants, even though there is no scientific basis for this concern (Miller, 2007). Because of this resistance, the large buyers of raw sugar have been requiring guarantees from the suppliers that the sugar supply is not derived from GM plants. This has created a wait-and-see approach, where sugarcane biotech research and development is ongoing but no one wants to be the first into the market. However, it is likely that sugar from sugarbeets engineered with herbicide and pest resistance traits will enter the market first and that will hopefully open the door for sugarcane. If GM sugarcane lines with doubled sugar production (Wu and Birch, 2007) perform well in field trials, pilot-scale production will most likely be trialed.

Refined white sugar (>99.98% sucrose) is the most chemically pure food produced from agriculture, thus, reducing any foundation for

concern about foreign genes or gene products in this food (Birch and Maretzki, 1993). Taylor *et al.* (1999) analyzed the various products during the crystallization process of sugar from sugarcane juice for the presence of transgene DNA. Their results showed that no PCR amplifiable DNA was present in sugar crystallized from SCMV transgenic plants.

However, when sugarcane is engineered as a biofactory to produce fine chemicals or pharmaceuticals, it is critical that clear safeguards are in place to ensure that there is no conceivable harm to public health or the natural environment. Safety evaluations will have to be done on a case-by-case basis. For instance, sugarcane producing bioplastic such as the pHBA and PHAs discussed in this chapter could still be used for production of sugars for human consumption. Animals already make pHBA and have the capacity to digest it (McQualter *et al.*, 2005), and PHAs have a 40-year history of safety in a variety of medical applications, especially because of biodegradability and biocompatibility. PHAs have been used for surgical sutures and wound dressings. There is ongoing research for the commercialization of PHA-based products for tissue engineering and for controlled release systems, and for bone repair (Zhijiang, 2006). Because these biopolymers in nature are used as a carbon sinks, they are fully biodegradable. So producing them in sugarcane should not be dangerous to human health or the environment.

3.4 Conclusions

Since the first successful report of transgenic sugarcane plants less than 20 years ago, biotechnology has advanced rapidly and been adopted by sugar industries and research organizations worldwide. Research into a range of input traits such as pest and disease resistance, sugar quality and shoot architecture, and output traits such as increased sucrose levels, alternative sugars, biopolymers, pharmaceuticals, and bulk proteins are ongoing. The future looks bright for sugarcane, as market forces drive the development of the bioeconomy, creating opportunities for sugar industry diversification and new partnerships with other global and local industries. A combination of factors, including but not limited to, global warming,

instability in the Middle East, concern over long term oil supplies, and the industrialization of China and India, have caused the world to look for alternatives to petroleum for fuel, energy, and fine chemicals. Governments have made plans, drawn up roadmaps, and set priorities for R&D funding to create ways to shift from a disproportional dependence on the nonrenewable resource petroleum. They are creating new industries and whole new economies based on renewable sources. The sugar derived from lignocellulosic biomass is going to be the renewable feedstock for the bioeconomy. The infrastructure is already being developed. Biorefineries are being constructed all over the United States, Europe and Brazil. Ethanol and a range of biopolymers are being produced in these biorefineries. In the United States, maize is the feedstock; in Brazil it is sugarcane. These nations all have R&D programs underway to switch over to biomass.

Developing new cultivars of sugarcane that will produce more tonnage, use less water and fertilizer, that will not fall down in a storm, can tolerate floods or drought, grow in the heat or the cold, are resistant to pests and diseases, can tolerate salt, can fight off weeds, and supply the majority of the world's needs for sucrose, and other sugars, bioplastics, and a host of other fine chemicals, reduce greenhouse gas, and clean up the environment is going to require considerable genetic manipulation. Systems biotechnology will help in the design strategies to manipulate the metabolic pathways of sugarcane. However, the ability to transform sugarcane with genes and/or metabolic pathways will be instrumental in helping sugarcane industries become drivers of the bioeconomy.

ACKNOWLEDGMENTS

Our special thanks to Dr Peter Allsopp from BSES Limited for his editing and advice on this book chapter. We also thank Drs Debra Stenzel (Analytical Electron Microscopy Facility, Queensland University of Technology, Australia) and Lars Petrasovits (Australian Institute for Bioengineering and Nanotechnology, The University of Queensland, Australia) for their assistance with the electron micrographs in Figure 5. Annathurai Gnanasambandam is a recipient of a "Smart

State Fellowship” awarded by the Department of State Development, Trade, and Innovation of the Queensland Government.

1. INTRODUCTION

1.1 Botanical Description: Distribution, Taxonomy, and Cytology

Beta vulgaris is an herbaceous, allogamous dicotyledon belonging to the Chenopodiaceae family. Annual and biennial genotypes of *Beta* exist; however, cultivated sugar beet is biennial. In its vegetative state, sugar beet produces a close spiral of triangular leaves with conspicuous midribs and petioles in a rosette on a compacted stem (crown) and a large fleshy tap root that is harvested for its sugar (sucrose). Reproduction is initiated by a cold vernalization period followed by long photoperiods (Smith, 1980; Klotz, 2005; Milford, 2006). The reproductive phase begins with the formation of a rosette similar to that described for the vegetative phase followed by the production of an aerial stem with flowering branches. Sugar beet has perfect flowers consisting of a tricarpellate pistil surrounded by five stamens and five narrow sepals. Flowers are sessile and occur singly or in clusters of two to seven. The ovary forms a fruit that contains a single seed. The ovaries of all flowers within a cluster are enclosed in a common receptacle. This produces a, so-called, multigerm seed. When flowers occur singly the fruit is commonly referred to as monogerm seed (Smith, 1987).

Sugar beet can be grown in many environments; however, most commercial production is between 30° and 60° North latitude. It is grown on a wide range of soil types as a summer crop in maritime, prairie, and semicontinental climates, as a winter or summer crop in Mediterranean environments, and under irrigation in semi-arid and arid environments. Sugar beet, a halophyte, exhibits considerable tolerance to soils with high salinity concentrations (Draycott and Christenson, 2003).

It appears that the genus *Beta* originated in middle eastern and eastern Mediterranean countries. Wild forms are found as far east as China and as far west as California (USA). The earliest records of beet domestication indicate that it was cultivated as a leafy vegetable in the Tigris and Euphrates river valleys between 2000 and 1500 BCE (Doney, 1995). The number of species within the genus depends upon the taxonomic treatment, but there is general agreement that *Beta* is comprised of four sections; *Beta*, *Corollinae*, *Procumbentes*, and *Nanae* (Coons, 1954, 1975; Smith, 1987; Jassem, 1991; Doney, 1995).

Section *Beta* is the most widely distributed and includes all cultivated forms of *Beta*. A recent classification scheme divides the section into three species: *B. vulgaris* L., *B. patula* Ait., and *B. macrocarpa* Guss (Letschert *et al.*, 1994). *B. vulgaris* is comprised of three subspecies. Subspecies *vulgaris* includes all cultivated forms

and is further divided into four cultivar groups (cultua): leaf beet, garden beet, fodder beet, and sugar beet. Subspecies *maritima* and *adanensis* are wild forms of *B. vulgaris*. *B. patula* is an isolated species, occurring only on a small island of Madeira. Within this section, *B. macrocarpa* is the most distantly related to sugar beet (Doney, 1995). All species of section Beta produce fertile offspring when intercrossed. Most members of this section are outcrossing due to self-incompatibility.

Section Corollinae species are found in areas of the Balkan Peninsula, Turkey, Transcaucasia, and Iran, generally at higher elevations than species of section Beta. This section is comprised of five species and includes diploid, autotetraploid, allotetraploid, and allohexaploid forms of which some are apomitic (Ford-Lloyd, 2005). All species are characterized by a corollalike perianth. There is little homology between chromosomes of sugar beet and species of Corollinae, and the interspecific hybrids are almost always sterile (Smith, 1987). Polyploid sugar beet parents and bridging hosts can sometimes be useful in introgressing traits from species in this section into sugar beet (Coons, 1975; Hadley and Openshaw, 1980).

Three species comprise the Procumbentes section. Some evidence suggests that two of these, *B. procumbens* Sm. and *B. webbiana* Moq., are not distinct species and the third species, *B. patellaris* Moq., is an autotetraploid derived from the *B. procumbens* morphological form (Ford-Lloyd, 2005; Skaracis, 2005a). The Procumbentes section is characterized by its annual growth habit and monogerm seed. Its distribution is limited to the Canary Islands. Species of this section usually produce sterile offspring in interspecific hybrids with sugar beet, but bridging hosts and polyploid sugar beet lines may facilitate the transfer of desirable traits (Coons, 1975; Hadley and Openshaw, 1980). Applied breeders are especially interested in this section because of the beet cyst nematode (*Heterodera schachtii* Schm.) resistance observed in some populations of Procumbentes (Coons, 1975; Halldén *et al.*, 1997; Skaracis, 2005b; Panella and Lewellen, 2006).

There is only one species, *B. nana* Boiss. et Heldr., in the Nanae section. *B. nana* is a diploid, characterized by small plants with rosettes of leaves less than 10 cm across (Smith, 1980). It is endemic to a few high-elevation environments in

Greece (Ford-Lloyd, 2005). No crosses between *B. nana* and sugar beet have been reported.

Sugar beet is a true diploid species with a haploid chromosome number of nine. The small size of the chromosomes, the absence of differentiating characteristics, and the unavailability of genetic stocks with chromosome aberrations made identification of individual chromosomes difficult without recent technology (Skaracis, 2005a). A complete set of primary trisomics (Romagosa *et al.*, 1986, 1987; Schondelmaier and Jung, 1997) is available for assigning genes to chromosomes and establishing linkage groups. Furthermore, a full set of *B. procumbens* and *B. webbiana* monosomic addition lines and eight *B. corolliflora* addition lines have been identified (Skaracis, 2005a). Colchicine has been used for at least 50 years to produce tetraploid sugar beet (Savitsky, 1966). When tetraploid pollinators are crossed with a diploid parental line, approximately 10% aneuploids will be present in the resulting commercial triploid hybrid seed. The advent of molecular markers has greatly expanded knowledge of linkage relationships in sugar beet (Pillen *et al.*, 1993; Barzen *et al.*, 1995; Halldén *et al.*, 1996; Schondelmaier and Jung, 1997; Rae *et al.*, 2000).

1.2 Economic Importance

Sugar beet is a significant industrial crop of the temperate zone, the worldwide production of which exceeded 240 million tons in 2000 (FAO, 2000). Worldwide, sugar from sugar beet provides about a third of all sugar consumed. Used as a sweetener in foods, beverages, and pharmaceuticals, sugar makes up about 11% of all food consumed in the world and its consumption has been growing at 2% per year, the same rate as the increase in world population (Wozniak, 1999). World acreage of sugar beet harvested is currently greater than 7.7 million hectares and is expected to increase to meet world demands. Market value of this crop is in the billions of US dollars. About half of all the sugar consumed in the United States comes from sugar beet roots. Over 26 million tons of sugar beet valued at over \$1.2 billion is produced each year in the United States on more than 0.6 million hectares. Due to its high productivity, sugar beet is increasingly being scrutinized not only as a source of sugar, but also

as a possible “green bioreactor”, i.e., for synthesis and accumulation of new metabolites in roots (Monger *et al.*, 1995; Sévenier *et al.*, 1998; Menzel *et al.*, 2003). The increase in world population taken together with the increased demand for alternative energy sources suggests a growing need for increased production of sugar beet not only as a source of food but also as a source of biofuels. This anticipated demand provides the motivation for development of innovative approaches, such as genetic modification through engineering to augment and complement classical breeding techniques.

1.3 Traditional Breeding

The transformation of fodder beet into sugar beet through selection was the basis for the early survival of the beet sugar industry. Since that time traditional plant breeding efforts have made notable contributions to reducing labor costs through the incorporation of the monogerm trait into commercial varieties, reducing the impact of diseases and pests on the crop, and increased productivity through the improvement of elite parental lines and the development of hybrid varieties.

Utilization of commercial sugar beet hybrids has allowed breeders to capitalize on the general occurrence of nonadditive genetic effects for root yield. Pollen sterility in the lines used as females depends upon a genetic-cytoplasmic interaction (cytoplasmic male sterility; CMS). Male-sterile plants have a sterile cytoplasm (S) and homozygous recessive alleles (xxzz) at two loci that control pollen development (S: xxzz). CMS lines require an equivalent pollen-fertile maintainer line (referred to as an O-type line in sugar beet) that has normal (N) cytoplasm and is recessive at the same two loci (N: xxzz). The development of CMS parental lines and their corresponding maintainer lines is facilitated by the introduction of a dominant gene that results in almost obligate self-fertility. Genetic male sterility, controlled by a single nuclear gene, is often introduced into O-type breeding populations to allow crossing among otherwise self-fertile plants (Smith, 1987; Biancardi *et al.*, 2005; Bosemark, 2006). Because monogerm seed is required in commercial production, all female parental

lines must be homozygous for the recessive gene that produces the monogerm phenotype. Parental lines to be used as pollinators in the production of commercial hybrids are almost always multigerm, because they produce more pollen than comparable monogerm plants. The genotype of pollinator parental lines with regard to the monogerm–multigerm trait or pollen-fertility restoration genes is not important.

A significant portion of the increase in sugar beet productivity over years can be attributed to improved varieties, and sustained profitability of the industry requires a continued emphasis on yield enhancement. Increasing sucrose concentration enhances processing efficiency but root yield (weight per area) is often the major component influencing sucrose yield per hectare. An inverse relationship between root yield and sucrose concentration has made simultaneous improvement of both difficult (Campbell, 2002). Furthermore, the optimum balance between root yield and sucrose concentration may depend upon payment calculations that often include premiums for roots with relatively high sucrose concentration. Genetic variance for sucrose concentration is predominately additive. In contrast, nonadditive variance and specific combining ability are significant in determining root yield. In addition to sucrose concentration, sugar beet quality also takes into account naturally occurring compounds that impede sucrose crystallization during normal factory operations (Dutton and Huijbregts, 2006). Selecting for increased sucrose concentration usually results in a concurrent reduction in these undesirable compounds.

Host plant resistance to diseases and pests has contributed to sugar beet productivity and in some cases allowed the crop to thrive in areas where the diseases and pests could not be controlled economically by other means (Smith, 1987; Biancardi *et al.*, 2005; Bosemark, 2006). For many diseases, resistance is not simply inherited and is not complete (immunity). As a result, resistance is usually combined with other control strategies to minimize damage. Identifying sources of resistance and selecting resistant plants from segregating populations frequently entails the establishment of specialized nurseries and/or the development of dependable inoculation techniques. Wild relatives of sugar beet are a potential source of pest resistance genes (Lewellen, 1992; Panella and

Lewellen, 2006); however, their use is complicated by the extended time and effort required to transfer the desired resistance to otherwise adapted genotypes (Stander, 1993). In some cases the triploid hybrid produced by crossing a resistant tetraploid pollinator with a susceptible CMS line may be more resistant than the comparable diploid hybrid (Hecker and Ruppel, 1976).

Mass selection based upon phenotype has been effective in enhancing resistance to some diseases, increasing sucrose content, and selecting for desirable root shape. Half-sib or full-sib (pair crosses) selection is often used by breeders, especially when self-incompatibility precludes selfing. Including a CMS tester in a small tent with the two plants in a pair cross will provide seed for initial combining-ability tests. Reciprocal recurrent selection, a procedure used in other cross-pollinated crops, is not readily applied to sugar beet as it requires plants be selfed as well as crossed. Doney and Theurer (1978) outlined a method that overcomes these obstacles by incorporating genes for self-fertility and genetic male sterility into source populations. Gametophytic (pollen) screening has been suggested as a selection method (Smith and Moser, 1985). In some situations, vegetative propagation or cloning may be used to perpetuate genotypes that are difficult to maintain with seed production (Saunders, 1982; Mezei *et al.*, 1990; Tsai and Saunders, 1995).

1.4 Limitations of Conventional Breeding

Although sugar beet breeders often can rely on the experiences of hybrid breeders in other allogamous crops for guidance, sugar beet has a unique combination of complicating characteristics that must be considered in the implementation of an applied breeding program. Developing a productive commercial sugar beet hybrid requires more time and resources than most other field crops.

The biennial growth habit of sugar beet may lengthen the time required for a selection cycle, compared to annual crops, and possibly limits the size of a breeding program. Vernalization requires refrigeration facilities or nurseries that frequently must be located in environments at some distance from production areas. *BvFL1* (*Beta vulgaris* flowering locus 1), the homolog of *Arabidopsis*

FLC, a repressor of flowering, was recently characterized in sugar beet. During vernalization, the gene is down-regulated permitting flowering to occur in beet. Efforts are underway to create a transient system for knocking out *BvFL1* to stimulate flowering in the absence of vernalization; a tool that could speed up the breeding process in the future (Reeves *et al.*, 2007). Sugar beet is normally self-sterile. This can be a problem when selfing would be beneficial, especially in the identification of O-type individuals in populations from which candidates for CMS parental lines are to be selected (Campbell, 2000; Biancardi *et al.*, 2005; Bosemark, 2006). Self-sterility can be overcome by the introduction of a self-fertility gene; however, if intermating is desired within or between populations homozygous for the self-fertility gene it is customary to introduce genetic male sterility. In addition, to be commercially viable, CMS lines must be homozygous for the gene controlling the monogerm trait. These requirements for female parental lines complicate the introduction of traits related to adaptation and productivity.

The origin and subsequent development of sugar beet varieties suggest that the genetic base of the crop is less diverse than many open-pollinated crops. The wild relatives of sugar beet likely possess many characteristics, particularly resistance to diseases, nematodes, insects, and abiotic stresses that would be beneficial in sugar beet (Lewellen, 1992; Doney, 1995; Panella and Lewellen, 2006). However, populations derived from crosses between sugar beet and its wild relatives have many undesirable traits that must be eliminated by selection and backcrossing to sugar beet (Stander, 1993). Marker-assisted selection (Skaracis, 2005b) can be helpful in selecting for one or a few genes that control a particular trait of interest (Halldén *et al.*, 1997) but are of limited value in eliminating most of the undesirable characteristics in an interspecific hybrid population. Selection for resistance to specific pests becomes more complicated as the number of loci conditioning the resistance increases (Bosemark, 2006). Most of the economically important traits and resistance to numerous pests and diseases are either quantitative or conditioned by multiple genes (Biancardi *et al.*, 2005).

Multienvironment trials with candidate sugar beet hybrids are similar to those used in other crops but require more resources than many other

crops (Fauchère *et al.*, 2002). The volume of seed required for widespread trials generally entails production at a site with winter temperatures sufficient for vernalization but not cold enough to significantly reduce winter survival (Kockelmann and Meyer, 2006). Often sugar beet harvest equipment for field plots is not commercially available and must be fabricated or modified locally.

2. DEVELOPMENT OF TRANSGENIC SUGAR BEETS

2.1 Rationale for Transgenic Sugar Beet

Transgenic sugar beet has the potential to overcome some of the constraints and difficulties associated with conventional breeding and accelerate the development of adapted productive commercial hybrids. In addition to allowing the transfer of genes from other *Beta* species without the introduction of undesirable traits (Cai *et al.*, 1997), genes from unrelated organisms could be utilized in sugar beet improvement. The successes in introducing genes from microorganisms that resulted in resistance to broad-spectrum herbicides have demonstrated the potential of transgenic sugar beet (Pidgeon *et al.*, 2005a, b). When sugar beet is grown in areas outside the natural range of the species, it is vulnerable to pathogens and pests that it had not encountered previously. When the attacking organism and the progenitors of sugar beet have not coevolved, resistance genes in *Beta* may be rare or nonexistent. In these cases, other organisms may contribute particularly valuable resistance genes. The possibilities of transgenic sugar beet are not limited to the introduction of resistance genes but include the modification of physiological process related to adaptation and yield, the production of new products of economic value, and the advancement of knowledge of basic sugar beet physiology (Wozniak, 1999; Lathouwers *et al.*, 2005; Skaracis, 2005b).

2.2 Tissue Culture and Regeneration

Genetic improvement via biotechnological approaches has progressed slowly in sugar beet because this crop is quite recalcitrant to regeneration

following genetic transformation (Snyder *et al.*, 1999; Ivic *et al.*, 2001; Ivic and Smigocki, 2003; Zhang *et al.*, 2004; Ivic-Haymes and Smigocki, 2005a; Norouzi *et al.*, 2005). To successfully apply gene transfer techniques for crop improvement, an efficient and reliable tissue culture regeneration system is generally a prerequisite. Attempts to enhance the regeneration potential of sugar beet via improved tissue culture conditions have been the subject of numerous studies reporting a range of outcomes. Various sugar beet cell and tissue explants used for regeneration of whole plants include axillary buds, cotyledons, epicotyls, hypocotyls, leaves, petioles, thin-layer epidermal strips, zygotic embryos, unfertilized ovaries, and leaf main veins of plantlets derived from cultured apical meristems as well as suspension cells derived from some of these various tissues (Hooker and Nabors, 1977; Rogozinska and Goska, 1978; Saunders, 1982; Bhat *et al.*, 1986; Steen *et al.*, 1986; Detrez *et al.*, 1988; Krens and Jamar, 1989; Ritchie *et al.*, 1989; Jacq *et al.*, 1993; Gurel and Gurel, 1998; Zhang *et al.*, 2001, 2004; Norouzi *et al.*, 2005). The potential for direct uptake of foreign DNA through electroporation or chemical (e.g., polyethylene glycol) treatment has been demonstrated in sugar beet with leaf and petiole-derived protoplasts (Bhat *et al.*, 1985; Lindsey and Jones, 1987, 1989; Krens *et al.*, 1990; Hall *et al.*, 1993, 1995, 1996b, 1997; Lenzner *et al.*, 1995). Hall *et al.* (1995, 1996a) demonstrated that stomatal guard cells were totipotent and useful source of cells for transformation and regeneration of transformed sugar beet plants from protoplasts (Hall *et al.*, 1996b). The manipulation of these wall-less cells, however, is troublesome as osmotic potential and physical handling become a primary concern prior to wall regeneration. Similarly, new culture conditions need to be established for protoplasts as they are distinct from those used with tissue or organ culture.

The regenerative capability of cultured sugar beet and other plant cells has been accomplished by alteration of growth regulators, e.g., type and concentration (Tetu *et al.*, 1987; Toldi *et al.*, 1996; Zhang *et al.*, 2001); physical factors, e.g., light, temperature, relative humidity, tissue support matrix, (Saunders and Shin, 1986; Owens and Wozniak, 1991; Elliot *et al.*, 1992; Hall *et al.*, 1993); chemical components, e.g., inorganic and organic nutrients (DeGreef and Jacobs, 1979; Freytag

et al., 1988); and physiological status of the explants (Saunders and Shin, 1986; Jacq *et al.*, 1992; Toldi *et al.*, 1996). A regeneration medium that was considered superior to other formulations in both callus induction and adventitious shoot formation was reported by Freytag *et al.* (1988). The medium included inorganic salts, 10 vitamins, 6 amino acids, sucrose, benzyl adenine, and indole-3-butyric acid. It was the combination of amino acids and vitamins that was determined to be critical for the observed enhancement. However, despite the success of this medium, highly variable rates of adventitious shoot formation were still observed and could not be overcome via tissue culture manipulation. Findings that emerged from all of these studies point to a more serious obstacle for establishing reproducible regeneration protocols, i.e., the influence of a particular genotype.

A major consideration when establishing a reliable and efficient transformation protocol is the recognition that transformation methods developed with model plants often fail when applied to elite lines; therefore, it is advantageous to initiate molecular breeding programs with lines of interest (Christou, 1995; Ivic and Smigocki, 2001). Early attempts to develop a model plant for sugar beet genetic manipulation studies yielded a tissue culture clone, REL-1, which was selected for its high frequency of shoot regeneration from leaf-derived callus (Saunders, 1998). However, since REL-1 does lack many agronomically important traits, numerous cycles of backcrossing are required to introduce transgenes into favorable genetic backgrounds (Saunders, 1998; Snyder *et al.*, 1999). Therefore, the identification of desirable germplasm with high regeneration potential is considered an important element for development of an efficient plant transformation method, particularly for recalcitrant crops, such as sugar beet. Since regeneration in sugar beet is strongly genotype dependent, selection of highly regenerative individuals from favorable genetic backgrounds is considered a prerequisite (Miedema, 1982a, b; Freytag *et al.*, 1988; Jacq *et al.*, 1992, 1993; Ivic-Haymes and Smigocki, 2005b). In addition, regeneration frequencies are significantly reduced, more so in the recalcitrant crops, by the transformation process. Inhibition of regeneration in sugar beet was shown early on for a highly regenerative sugar beet line, AN5, following co-cultivation with *Agrobacterium*

tumefaciens that was used to transform it (Krens *et al.*, 1988).

Variations in regeneration from leaf cultures of up to four individual plants from five breeding lines were reported by Saunders and Doley (1986). Similar results were also obtained when petioles from individual plants of 12 breeding lines were cultured (Saunders and Shin, 1986). A study focused on a larger number of individual plants (up to 34) of seven elite lines characterized by relatively high sugar content and disease resistance traits (Smith and Ruppel, 1980; Panella, 1999; Lewellen, 2000) identified a wide range of regeneration frequencies (Ivic-Haymes and Smigocki, 2005b). Individual plants within each line were phenotypically identical, but they still exhibited a wide range of shoot regeneration responses (Table 1). The widest range was observed within FC607 (19–100%), in contrast to REL-1 (63–100%). In addition, large deviations were observed in the mean percentage of adventitious shoots that regenerated from leaf disks derived from plants that were preselected for a positive regeneration response (Table 1). Shoot regeneration frequencies ranged from 8% to 56% as compared to greater than 80% for REL-1. FC607 had the highest mean number of shoots, 8, which regenerated per excised explant (Table 1).

Determination of the regenerative potential can be made at an early stage of plant development (Ivic-Haymes and Smigocki, 2005b). Highly regenerative plants were identified among 3-week-old seedlings using explants from fully expanded

Table 1 Adventitious shoot formation on leaf explants from seven sugar beet breeding lines and a highly regenerative, tissue culture-selected line REL-1^(a)

first pairs of true leaves. This regeneration potential was stably maintained for at least a few years in vegetatively propagated plants. Once regenerated shoots were rooted and transferred to the greenhouse, vegetative propagation through tissue culture was employed to expand the source of highly regenerative donor material needed for transformation experiments (Ivic-Haymes and Smigocki, 2005b). Even though other studies have shown that the stability of the adventitious regenerants from leaf explants may exhibit somaclonal variation (Saunders and Doley, 1986; Saunders *et al.*, 1990), *in vitro* leaf explant responses were found to be comparable to the respective source genotypes with no detectable phenotypic changes (Ivic-Haymes and Smigocki, 2005b).

Variations in morphogenic capacity among individuals within a cultivar have been reported in spinach, cotton, alfalfa, and red clover (Keyes *et al.*, 1980; Matheson *et al.*, 1990; George and Tripepi, 1994; Kumar *et al.*, 1998; Ishizaki *et al.*, 2001; Mishra *et al.*, 2003; Moltrasio *et al.*, 2004). The variable response observed within the sugar beet breeding lines reflects the fact that sugar beet is an open-pollinated species and most lines are a heterogeneous mixture of genotypes (Bosemark, 2006). However, even though genetically identical plants like REL-1 were obtained by axillary shoot propagation *in vitro*, they still exhibited differences in their regeneration potential that likely were the result of differences in the physiological state of these plants. The interactions between genetic background, physiology, medium composition, and growth conditions on the regeneration potential are well documented. It is imperative, therefore, that individual plants within a line of interest be tested in order to identify the high regenerators that could be used for molecular breeding and improvement programs. In addition, the selection of lines with enhanced regeneration capacity should advance our understanding of *in vitro* capabilities, particularly as they relate to regeneration of plants from callus tissue or suspension culture.

2.3 Transformation Methods

A reproducible and efficient method for regeneration of transgenic sugar beet plants has

not been developed, although years of efforts have been expended to improve its recalcitrance to transformation (Table 2; see for review Wozniak, 1999; Lathouwers *et al.*, 2005). Most recently, reported methods include *Agrobacterium*-mediated transformation of shoot-base tissues (Lindsey and Gallois, 1990; Hisano *et al.*, 2004), cotyledonary node explants (Krens *et al.*, 1996; Joersbo *et al.*, 1998; Lennefors *et al.*, 2006), shoot explants (Zhang *et al.*, 2001) or embryogenic callus (D'Halluin *et al.*, 1992; Zhang *et al.*, 2001) as well as particle bombardment of embryogenic callus (Snyder *et al.*, 1999; Ivic and Smigocki, 2003), and polyethylene glycol-mediated transformation of guard cell protoplasts (Hall *et al.*, 1996a; Lauber *et al.*, 2001). Frequency rates for obtaining transformants ranged from 0.0001% to 0.0007% for guard cell protoplasts (Hall *et al.*, 1996b) and were higher than 30% for bombarded embryogenic hypocotyl callus (Snyder *et al.*, 1999). In general, sugar beet transformation methods are labor intensive and require a relatively long time for explant preparation and subsequent regeneration of transgenic plants. For example, the method of D'Halluin *et al.* (1992) requires 2–3 months for generation of seedling-derived callus for transformation, followed by sequential transfer of tissues to five different media throughout the procedure. The method of Snyder *et al.* (1999) similarly entails several lengthy (2–3 months) and labor-intensive steps for plant material preparation, including a seed germination step that is often plagued by high levels of contamination. As with the method reported by D'Halluin *et al.* (1992), several transfers of tissues were required and plants regenerated only after about 6 months in culture. Most methods have not been found readily applicable in laboratories other than those in which they were developed (Krens *et al.*, 1996; Snyder *et al.*, 1999; Smigocki, unpublished results). The method of Snyder *et al.* (1999) proved ineffective for transformation of several commercial sugar beet breeding lines (Ivic and Smigocki, 2001). Although proprietary methods that include *Agrobacterium*-mediated transformation of cotyledons have been reported to generate transgenic plants, in general, these methods are not well described and require high input due to their low efficiency (Fry *et al.*, 1991; Krens *et al.*, 1996). Although low in efficiency

^(b) Calculated as number of transformed shoots per number of explants or protoplasts

relative to some other dicotyledonous plants, the method of D'Halluin *et al.* (1992) was the first to provide a sufficient number of transgenic sugar beets suitable for further evaluation in an agronomic field test.

A recently developed method uses highly regenerative leaf callus suspension cultures derived from commercial breeding lines that were first identified as being highly regenerative (Table 1; Ivic and Smigocki, 2003). When these suspension cells were subjected to particle bombardment, transformed embryos and callus lines regenerated starting at 5 months of culture but no transgenic plants were recovered. Such long tissue culture periods have been associated with the inhibition of the organogenic potential in transformed tissues (Cassells and Curry, 2001) as well as higher frequencies of abnormal phenotypes and reduced fertility in transgenic plants (Altpeter *et al.*, 1996; Cassells and Curry, 2001; O'Kennedy *et al.*, 2001). To circumvent these problems and reduce the time in culture, leaf disks from the highly regenerative plants were used as target tissue for particle bombardment immediately after excision from the leaves (Ivic-Haymes and Smigocki, 2005a). This relatively simple and time-saving procedure yielded transformed plants as early as 3 months after bombardment at a frequency of 0.9–3.7%. In addition, since frequent transfer of leaf disks to fresh medium was shown to have a negative impact on regeneration (Ivic-Haymes and Smigocki, 2005b), this method also proved to be less labor-intensive and costly since bombarded explants were only transferred to fresh media every 3–4 months.

Unlike the method of Ivic-Haymes and Smigocki (2005a), Hisano *et al.* (2004) recently developed yet another method that is entirely dependent on tissue culture. This *Agrobacterium*-mediated gene transfer method utilizes shoot-base cultures as target tissues for transformation but is deemed simpler than the previously published shoot-base method (Lindsey and Gallois, 1990; Konwar, 1994). Leaf blades excised from young plants are cultured on shoot formation medium until shoots regenerate on the veins. Shoot bases are then stripped of the shoots and used as explants for transformation. The regeneration frequencies were reported to be consistent and as high as 30%, thus contributing to the production of uniform transgenic plants from several lines

of *B. vulgaris* as well as *B. maritima* accessions. Two different *Bacillus thuringiensis* (*Bt*) genes and a chitinase gene were introduced along with an *nptII* (neomycin phosphotransferase II) gene as the selectable marker for kanamycin resistance. In addition, the *hpt* (hygromycin phosphotransferase) gene was used as a selectable marker to regenerate the first hygromycin resistant transgenic sugar beet. An important advantage of this method is the reported lack of an intervening callus phase that often is linked to the occurrence of somaclonal variation. Other reports of direct shoot regeneration include *Agrobacterium*-mediated transformation of cotyledons with a soybean cercosporin toxin export gene, *cfp*, which is being evaluated for its potential role in *Cercospora* leaf spot resistance (Kuykendall *et al.*, 2003).

A method reported by Yang *et al.* (2005) utilized tissue-cultured bud tips derived from immature inflorescence to introduce salt tolerance into sugar beet. Vigorously growing bud clumps were induced on the cultured inflorescence. Buds were excised from the clumps and after 7 days of culture, bud meristems were exposed by removal of the leaves from the buds. *Agrobacterium*-mediated gene transfer method was used to transform the exposed meristems. Attempts to optimize the transformation frequency included the use of various concentrations of *Agrobacterium* for infection, varying the duration of the co-cultivation period, infecting the buds under variable negative pressure and adding varying concentrations of a surfactant (Silwet L-77) during co-cultivation. These permutations enhanced the overall frequency of regeneration of transgenic plants that were able to grow at higher salt concentrations.

Transgenic sugar beet resistant to a glufosinate herbicide have also been produced using an *Agrobacterium* vacuum infiltration transformation method (Kishchenko *et al.*, 2005). Target tissues included etiolated seedlings or suspension cultures that were prepared from friable hypocotyl and cotyledon callus of two breeding lines. After the seedlings were vacuum infiltrated, a similar procedure was used to generate friable callus from the hypocotyls and cotyledons. Transgenic plants regenerated from the transformed callus after 4–10 weeks on phosphinothricin-containing selective medium.

2.3.1 Hairy root cultures

The regeneration of transformed sugar beet hairy root cultures has provided an *in vitro* approach for detailed studies of a variety of agricultural problems associated with sugar beet production. Hairy root cultures are derived via *Agrobacterium rhizogenes*-mediated transformation of seedling hypocotyls or petioles (leaf stalks) (Tepfer, 1984; van der Salm *et al.*, 1996; Kifle *et al.*, 1999; Cai *et al.*, 2003; Smigocki *et al.*, 2006). The advantage of hairy root cultures is that they provide a rapid means (generally less than 3 weeks) for obtaining transformed sugar beet tissues that express foreign genes of interest. This approach provides for a rapid functional analysis of gene function *in planta*. Generation of transgenic plants that express the most interesting genes will still require the traditional labor-intensive and time-consuming transformation approaches since sugar beet hairy roots are recalcitrant to regeneration (Smigocki, unpublished results). The beet necrotic yellow vein virus (BNYVV) coat protein (CP) gene was initially evaluated in sugar beet hairy roots as a precedent for introducing BNYVV resistance into transgenic sugar beet (Ehlers *et al.*, 1991; Mannerlöf *et al.*, 1996). Similarly, Cai *et al.* (1997) generated transformed hairy roots with a complementary DNA clone *HsI^{pro-1}* from *B. procumbens*, a beet cyst nematode (*H. schachtii*)-resistant species, and observed incompatible reactions (no cyst development) in several independent transformants derived from susceptible lines.

Sugar beet hairy root cultures have been effectively utilized for studying plant–pathogen and plant–pest interactions *in vitro*. Mugnier (1987) examined the infection of transformed roots of sugar beet and table beet by *Polymyxa betae* and of brassicas by *Plasmodiophora brassicae*. He was able to identify two distinct fungal phases in the infected hairy root cultures. The culture of these obligate parasites on transformed roots allowed for detailed life cycle descriptions not previously obtainable under axenic conditions. Preliminary experiments with *H. schachtii* indicated that the larvae were capable of forming new cysts without loss of pathogenicity when cultured on sugar beet hairy root cultures (Paul *et al.*, 1987). An *in vitro* approach was also used to demonstrate resistance to *H. schachtii* in a modified nematode-

resistant sugar beet line, AN5 (Paul *et al.*, 1990). Detailed observations of sugar beet root maggot (SBRM, *Tetanops myopaeformis*) larval-feeding behavior and evaluation of the influence of bacterial additions on larval development were similarly evaluated using axenic hairy root cultures (Wozniak, 1993). In the same way, hairy root bioassays were used for *in vitro* testing of toxic *Nicotiana tabacum* extracts on SBRM survival (Smigocki *et al.*, 2003).

As the methods presented above and those under development are refined, it is clear that steady increases in transformation efficiency will occur. Improved transformation efficiencies will lead to a more rapid development of transgenic sugar beet with agriculturally desirable traits.

2.4 Selection of Transformed Tissue

2.4.1 Selectable marker genes

2.4.1.1 Antibiotics

As summarized above, the efficiency of sugar beet transformation is influenced by a multitude of factors, among them plant genotype and explant source (Table 2) being of paramount importance. Methods employed for selection of transformed cells appear to be equally important in the success of all transformation techniques. Antibiotic selection, which allows for specific enrichment for transformed cells, is generally considered an integral part of a transformation protocol. A widely used selection scheme in transgenomics incorporates an *nptII* selectable marker gene into the targeted cells making them resistant to kanamycin and other related antibiotics such as the aminoglycoside G418 (Geneticin). A high rate of nontransgenic escapes is often reported when antibiotics or herbicides are used as selective agents due to high levels of inherent tolerance to the selective agent (Lindsey and Gallois, 1990; D'Halluin *et al.*, 1992; Ivic-Haymes and Smigocki, 2005a). Another major drawback to the use of antibiotics is that they have been reported to severely repress the subsequent regeneration of transgenic plants (Everett *et al.*, 1987; Mullins, 1990). Use of kanamycin for selection of transformed sugar beet tissues has also proven to be difficult. A general delay in

regeneration of transformed calli on kanamycin-containing media was observed when sugar beet suspension cultures were subjected to particle bombardment transformation (Ivic-Haymes and Smigocki, 2005a). Culture of explants for about 4 months on 100 mg l^{-1} kanamycin yielded no calli or shoots. Contrary to these findings, Hisano *et al.* (2004) attributed their high transformation rate in part to the relatively high (150 mg l^{-1}) concentration of kanamycin in the selection medium. They report that supplementing the medium with phytohormones (6-benzylaminopurine (BA) and indole-3-butyric acid (IBA)) and using half-strength Murashige and Skoog (MS) salts contributed to the improved selection efficiency without disturbing the morphogenic ability of the sugar beet cells on kanamycin-containing media. Krens *et al.* (1996) selected transformed cells on even higher concentrations of kanamycin (250 mg l^{-1}) and maintained regenerated shoots on 200 mg kanamycin per liter. The variable responses of sugar beet tissues to kanamycin selection underscore the important roles that genotype and explant source play in the regeneration potential of transformed sugar beet.

To date, most reports on sugar beet transformation utilize vectors that carry the *nptII* selectable marker gene (Table 2). These transformation vectors represent the first generation of vectors that are widely distributed and, therefore, generally easily obtainable because their use is often not restricted by intellectual property rights. A relatively new class of transformation vectors that carry the *hpt* gene for selection of transformed cells on hygromycin-containing media is being used in sugar beet transformation (Hisano *et al.*, 2004; Yang *et al.*, 2005; Smigocki, 2008). Hisano *et al.* (2004) reported that hygromycin selection was effectively utilized for regenerating transgenic *B. maritima* plants from one of the two accessions that they tested. They were not successful at regenerating transgenic plants from three *B. vulgaris* lines. Yang *et al.* (2005), however, did regenerate hygromycin-resistant plants from several *B. vulgaris* accessions transformed with the *hpt* gene. Similarly, hygromycin-resistant hairy roots were regenerated from two *B. vulgaris* breeding lines (Smigocki, 2008). The observed differences in the generation of transgenic sugar beet most likely reflect genotypic differences, explant source and transformation method employed.

2.4.1.2 Herbicide

As a desirable field trait and a useful selectable marker, the advent of herbicide resistance genes is considered a significant enhancement in the selection of transformed cells (Perez *et al.*, 1989; Catlin, 1990; Joersbo and Okkels, 1996). Herbicide resistance has been introduced into sugar beet using three different genes that are involved in mediating the resistance: mutant acetolactate synthase (*als*) or 5-enolpyruvylshikimate-3-phosphate synthase (*epsps*) genes and the phosphinothricin acetyl transferase (*pat*; *bar*, bialaphos resistance) gene (Table 2; D'Halluin *et al.*, 1992; Mannerlöf *et al.*, 1997; Kishchenko *et al.*, 2005). D'Halluin *et al.* (1992) transformed embryogenic calli derived from cotyledons, hypocotyls, petioles, and leaves of sugar beet seedlings with *A. tumefaciens* carrying the *bar* or mutant *als* genes. They used kanamycin (200 mg l^{-1}) for initial selection of *bar* or mutant *als* transformants followed by selection for resistance to broad-spectrum herbicides glufosinate-ammonium (phosphinothricin, 20 mg l^{-1}) or to sulfonylurea (chlorosulfuron, 2 mg l^{-1}) compounds, respectively. The PAT enzyme acetylates and inactivates the herbicide (De Block *et al.*, 1987) while the mutant ALS makes the transgenic plant insensitive to the herbicidal compounds. Similarly, Mannerlöf *et al.* (1997) utilized the mutant *epsps* and a glyphosate oxidase reductase (*gox*) gene for selection of transformed cells resistant to the herbicide glyphosate (N-phosphonomethyl-glycine). The introduction of a mutant EPSPS enzyme into plants impedes the action of the herbicide that normally targets and inhibits the endogenous EPSPS in plants (Steinrücken and Amrhein, 1980). Gox provides an additional offensive line of protection by degrading glyphosate and reducing the total amount of the herbicide that can reach the target EPSPS (Dill, 2005). Herbicide selection proved effective for recovery of transgenic sugar beet that also possesses functional utility in realistic field and greenhouse situations.

2.4.1.3 Cytokinin

Selection schemes that rely on antibiotic or herbicide resistance genes for production of field-released transgenic crops have raised concerns

regarding their impact on the environment and their safety for human consumption. An alternate selection system introduces a β -glucuronidase gene as a selectable marker that releases the active growth hormone cytokinin from inactive cytokinin glucuronides in transgenic cells (Joersbo and Okkels, 1996; Okkels *et al.*, 1997). Release of the cytokinin stimulates growth and regeneration of transformed shoots. Transformation was reported to be two to three times more efficient than with kanamycin selection. Although sugar beet contains an endogenous β -glucuronidase (Wozniak and Owens, 1994), this should not preclude application of this system to sugar beet. Conjugated glucuronides may afford an alternative selection technique that avoids some of the potential problems associated with cosuppression and *trans*-inactivation. On the other hand, this approach is sensitive to variations in endogenous cytokinin levels as well as those used in *in vitro* culture of sugar beet, and fine-tuning it for generating transgenic plants may prove to be more complicated and time consuming. Another cytokinin approach based on the expression of a bacterial isopentenyl transferase (*ipt*) gene that catalyzes the first committed step in cytokinin biosynthesis has been developed for generating marker-free transgenic plants (Ebinuma *et al.*, 1997). Increased synthesis of cytokinin mediated by the *ipt* gene has been reported to enhance regeneration of transformed cells (Smigocki and Owens, 1988).

2.4.1.4 Mannose

A novel selection technique, based on the concept of favoring the growth of transgenic cells while starving, rather than killing, the nontransgenic cells, is the mannose selection system. The approach exploits the inability of most plant cells to utilize mannose as a carbon source and the expression of a bacterial gene coding for a phosphomannose isomerase (*pmi*) as a selectable marker gene (Okkels and Whenham, 1993; Okkels *et al.*, 1994). Mannose selection was demonstrated to be particularly efficient for regeneration of transgenic sugar beet (Joersbo *et al.*, 1998, 1999; Lennefors *et al.*, 2006). Transformed sugar beet cells that were capable of using mannose as a carbon source were positively selected for

enhanced growth while nontransformed cells were nutrient deficient, but not killed initially. This last point, wherein nontransformed cells do not die and release their potentially toxic cellular contents during selection, is believed to be of major significance for providing a more compatible environment for growth of transformed cells.

2.4.2 Reporter genes

Several markers have been developed for use as a visually screenable phenotype in transgenic plants. Marker genes that have been expressed in sugar beet for detection of transformed cells are encoded by the *gusA* (β -glucuronidase; *uidA*, GUS), *luc* (luciferase, LUC), and *gfp* (green fluorescence protein). The *gusA* gene is being used extensively for optimizing transformation conditions and for the confirmation of stable integration of newly introduced transgenes into plant genomes. By far, *gusA* has been the most frequently expressed reporter gene in transformed sugar beet (Table 2). In addition to monitoring for transformation, the *gusA* reporter gene serves as a powerful tool for determining temporal and tissue-specific expression patterns of gene promoters. Analysis of GUS to LUC activity in bombarded sugar beet cell suspension cultures revealed that the expression driven by the osmotin (*Osm*) gene promoter was about 2.5 times higher than that driven by the constitutive cauliflower mosaic virus (CaMV) 35S promoter (Ingersoll *et al.*, 1996). In addition, when embryogenic suspension cultures were bombarded with the *Osm-gusA* gene construct, chimeric expression was detected in transformed calli suggesting that the calli arose from both transformed and normal cells or that the *gusA* gene became silenced in certain parts of the transformed calli (Ivic and Smigocki, 2003). Similarly, expression of the *Osm-gusA* gene in sugar beet plantlets, greenhouse-grown plants, and hairy roots revealed various patterns and levels of GUS activity useful for construction of transgenes in order to achieve spatial and/or temporal regulation of expression *in planta* (Figures 1a–e; Ivic-Haymes and Smigocki, 2005a).

Recently, *luc* gene expression was documented in transgenic sugar beet taproots using root-specific gene promoters (Oltmanns *et al.*, 2006). The *luc* gene was chosen over the *gusA* reporter

Figure 1 (a) GUS activity in Osm-*gusA* shoot, (b) leaves and (c) trichomes of tissue culture-propagated Osm-*gusA* sugar beet plantlets; (d) epidermal and stomatal cells of a greenhouse-grown plant; and (e) hairy roots transformed with a *Medicago truncatula* root-specific promoter fused to *gusA* [Source: Ivic-Haymes and Smigocki (2005a). © Springer; Smigocki, unpublished results]

gene because sugar beet roots contain high levels of phenolic compounds that have been reported to inhibit the β -glucuronidase enzyme encoded by the *gusA* gene (Vainstein *et al.*, 1993). The GUS and LUC activity assays, however, are invasive and cannot be used to monitor gene expression *in vivo* in the same material over time. The *Aequorea victoria gfp* gene can function in a range of heterogenous environments and it is not a destructive assay. Analysis for GFP activity is monitored with blue or UV light for emission of fluorescence thus no tissues are destroyed in the process. The first and only successful detection of *gfp* gene expression in sugar beet was reported by Zhang *et al.* (2001). They employed the *sgfp-S65T* construct that had been optimized to give improved signals in plant cells (Chiu *et al.*, 1996). This approach for identifying transgenic sugar beet is considered advantageous

for enhancing regeneration and plant regeneration in the absence of selectable agents such as antibiotics and herbicides that are known to reduce regeneration frequencies and negatively impact public acceptance of genetically modified (GM) plants.

2.4.3 Promoters

Use of appropriate promoters for regulating transgene expression in plants is critical to the success of the transformation. Constitutive as well as tissue-specific and/or inducible promoters have been used to direct transgene expression in sugar beet (Table 2). The constitutive promoters 35S from the CaMV as well as the ubiquitin3 (Ubq3) from the ubiquitin gene have been used extensively in sugar beet to drive expression of

selectable marker, reporter, and beneficial genes. However, comparison of the 35S constitutive promoter to several inducible promoters for potential impact on gene expression revealed other strong promoters that may be more useful for driving the expression of beneficial genes in sugar beet cells (Ingersoll *et al.*, 1996). When *gusA* gene expression from the 35S, PR-S, osmotin, and a proteinase inhibitor (PinII) promoter was followed over a 48-h period, steady state levels of expression were reached with all promoters 12 h after DNA transfer (Ingersoll *et al.*, 1996). The 35S and PinII promoters reached similar levels of expression; the PR-S promoter, from a systemic acquired resistance gene, expressed at approximately 50% higher level than the 35S and PinII promoters; and the osmotin promoter proved superior in that the expression levels at 12–48 h after bombardment were approximately 2.5 times those of 35S.

Several sugar beet promoters have been cloned and characterized for tissue-specific expression. A chlorophyll a/b binding protein promoter expressed the *gusA* gene at high levels in leaves of transgenic sugar beet (Stahl *et al.*, 2004). Three other promoters had a root-specific expression pattern (Oltmanns *et al.*, 2006). A linker histone variant and a thaumatinlike protein gene promoter had expression restricted to the vascular tissue of the root, while the major latexlike gene promoter was expressed throughout the entire root. This technology holds promise for expressing genes in a tissue-specific manner without imparting deleterious effects on nontarget tissue.

2.5 Transgenics Developed

2.5.1 Herbicide resistance

Weed control is a costly and necessary part of sugar beet production, relying heavily on several postemergence herbicide treatments with or without a pre-emergence herbicide applied at planting. Herbicide costs ranged from 171 to 319 US dollars per hectare (Kniss *et al.*, 2004) with additional costs for cultivation and hand labor required to remove weeds not controlled with herbicides. Use of transgenic herbicide-resistant sugar beet could provide producers with broad-spectrum weed control at a fraction of the current cost for efficacious weed control in

this crop (Kniss *et al.*, 2004). The glyphosate-resistant sugar beet (Roundup Ready[®]) developed using a combination of an *Agrobacterium* sp. *cp4 epsps* and a *gox* gene (Mannerlöf *et al.*, 1997) was approved for production in the United States in 1998 (Duke, 2005). Transgenic sugar beet resistant to a glufosinate herbicide (Liberty Link[®]) has also been produced (Kishchenko *et al.*, 2005). Glufosinates inhibit glutamine synthase, thereby disrupting nitrogen metabolism. Introduction of the *bar* gene creates resistance to the glufosinate herbicide. The *bar* gene encodes a phosphinothricin acetyl transferase, which acetylates and inactivates the herbicide (De Block *et al.*, 1987). Although not extensively examined in sugar beet, *bar* expression in other crops did not affect nutritional composition (Oberdoerfer *et al.*, 2005).

2.5.2 Disease resistance

Cercospora beticola is a devastating, photoactive toxin-producing foliar fungal pathogen of sugar beet (Daub and Ehrenshaft, 2000). Tolerance to the fungus is a quantitative trait with low heritability (Nilsson *et al.*, 1999; Schäfer-Pregl *et al.*, 1999). Additionally, *C. beticola* has developed resistance against several major fungicides used for control (Bugbee, 1995; Windels *et al.*, 1998), therefore, novel disease control strategies are highly desirable. *A. tumefaciens* was used to deliver a chloroplastic and cytosolic superoxide dismutase from tomato into sugar beet (Tertivanidis *et al.*, 2004). Overexpression of the antioxidant superoxide dismutase created greater tolerance to *Cercospora* leaf spot and the fungal toxin cercosporin. Transgenic plants exhibited 70% less damage following exposure to cercosporin, and disease severity caused by *C. beticola* was reduced by 50%. In addition, tolerance to oxidative stress was enhanced in transgenic plants exposed to the herbicide methyl viologen. Another recently reported approach for imparting resistance to *Cercospora* leaf spot in sugar beet is based on the expression of the cercosporin toxin export (*cfp*) protein gene from *C. kikuchii*, the causative agent of purple seed stain in soybean (Kuykendall *et al.*, 2003). *Agrobacterium*-mediated gene transfer was employed for the introduction of the *cfp* gene into sugar beet, but the

resistance of the transgenic plants to *Cercospora* leaf spot was not reported.

Plants harboring defense-related genes encoding cecropin MB39, osmotin, DB4 thionin, and PR-S were regenerated from bombarded embryogenic hypocotyl calli of the tissue culture line REL-1 (Snyder *et al.*, 1999). These transformants were generated in an effort to provide resistance to a variety of bacterial and fungal pathogens, particularly *Erwinia carotovora* ssp. *betavascularum* that causes root rot, *C. beticola*, the causative agent of leaf spot, and *Rhizoctonia solani* AG2-2 that causes seedling root rot. However, preliminary analysis of transgenics for *Cercospora* leaf spot resistance showed that these plants were more susceptible to this pathogen than the controls. In addition, since the defense-related genes were introduced into the REL-1 tissue culture line, transgenic plants that show promising levels of resistance will need to be crossed with elite breeding lines. Otherwise, the genes will need to be transferred directly into advanced breeding lines for further evaluation.

BNYVV causes rhizomania, a devastating disease of sugar beet, which is transmitted by a soilborne fungus, *Polymyxa betae*. Moderate levels of BNYVV resistance have been introgressed to commercially important breeding lines (Lewellen and Whitney, 1993). Most recently, genetic engineering approaches are being applied to enhance tolerance to BNYVV (Mannerlöf *et al.*, 1996; Maleki *et al.*, 2003; Lathouwers *et al.*, 2005; Lennefors *et al.*, 2006). Expression of modified and, therefore, dysfunctional BNYVV movement protein (P15 TGB) genes driven by a constitutive promoter were introduced into sugar beet (Lauber *et al.*, 2001). When challenged with the virus, a number of the transformants were resistant. CP gene-mediated resistance was also reported by Maleki *et al.* (2003) and Mannerlöf *et al.* (1996), where the titer of BNYVV was shown to be reduced in the transgenic plants. A double-stranded RNA (dsRNA)-based resistance has recently been reported to be superior to the CP-mediated resistance (Lennefors *et al.*, 2006). Transgenic plants expressing an inverted repeat of a short fragment derived from the BNYVV replicase gene displayed higher levels of resistance than the CP-transformed plants. Even though the replicase gene fragment was obtained from a B-type isolate of BNYVV, transgenic

plants showed high levels of resistance against the A- and P-types BNYVV, thus illustrating the broad spectrum of the obtained resistance. This cross-reactivity between pathotypes may be a result of the high degree of conservation of the targeting sequence between viral isolates (Koenig and Lennefors, 2000). RNA silencing induced resistance does not rely on the accumulation of viral proteins, therefore, extensive toxicity or allergenicity studies on the transgenic plants may not be required thus facilitating their more rapid regulatory approval for large-scale commercial production and acceptance by the general public.

2.5.3 Alternative sweeteners

Low-calorie sweeteners are in high demand. Laboratory-based production of artificial sweeteners can be time consuming and expensive. To produce fructans in sugar beet, Sévenier *et al.* (1998) and Weyens *et al.* (2004) introduced the gene encoding 1-sucrose:sucrose fructosyl transferase (1-SST) from Jerusalem artichoke or onion, respectively, into sugar beet. This enzyme catalyzes the degradation of sucrose into low molecular weight fructans, a sugar substitute that is not metabolized by humans and promotes growth of beneficial digestive microorganisms. Introduction of 1-SST had no deleterious effect on plant growth and the tap root dry weight was unaffected in the transgenic line. Sévenier *et al.* (1998) reported that on average the transgenic plants produced 110 μ M (micromole) fructan per gram fresh weight, which is equivalent to 40% of the root total dry weight. An overall decrease in storage carbohydrates was observed in the Sévenier *et al.* (1998) study, and Weyens *et al.* (2004) speculated that this may have been due to the different expression level of the gene driven by two different constitutive promoters, 35S versus Ubq3. These observations suggest the fructan producing sugar beet may be a viable alternative to laboratory production of alternative sweeteners.

2.5.4 Salt tolerance

Sugar beet normally grows in soils with <103 mM salinity. In order to grow sugar beet in high-salt soils in China, Yang *et al.* (2005) overexpressed

the *Arabidopsis thaliana* Na^+/H^+ antiport gene (*Atnhx1*) in beet plants. The *Atnhx1* gene transports superfluous Na^+ from the cytosol to the vacuole thus making the plants more salt tolerant. Using three cultivars of beet that already were more salt tolerant when grown in 171 mM NaCl, Yang *et al.* (2005) generated transgenic plants expressing the *Atnhx1* gene that were able to tolerate up to two and a half times higher salt concentrations (427 mM NaCl). Using this approach, new high-salt-tolerant cultivars are likely to be created for exploiting saline soils for cultivation of sugar beet.

2.5.5 Frost tolerance

Chinese researchers from the Inner Mongolia Sugar Beet Manufacturing Research Institute and Department of Biology of Inner Mongolia University have transferred a frost tolerance gene from fish to sugar beet, which has made the plant more tolerant to cold temperatures (Yuancong, 1997). Using this transgenic technology will allow for a longer growing season and later harvest of beets in the northern growing regions. The transgenic lines extended the growing season 30 days beyond that of the control varieties and were able to withstand temperatures reaching -6°C to -6.5°C .

2.5.6 Regeneration potential

In hopes of improving the regeneration capacity of *B. vulgaris* by increasing endogenous cytokinin levels, Krens and colleagues (Krens *et al.*, 1988) were first to utilize “shooter” mutants of *A. tumefaciens*, wherein the auxin locus of the transfer-DNA region was inactivated but the cytokinin biosynthesis (*ipt*) gene was left intact. Although nine sugar beet lines were evaluated, no shoot regeneration from inoculated leaf discs was observed. When seedling tissues were used as explants, shoot regeneration was observed at low frequencies, but transformation was not confirmed. In an analogous attempt to enhance regenerative ability of transformed REL-1 cells (leaf discs, suspension cells) and “FC607” (petioles, leaf discs), explants were inoculated with a supervirulent *A. tumefaciens* strain EHA101

carrying the *ipt* gene on a binary vector (Smigocki and Owens, 1988; Wozniak and Owens, 1989). Although transformed cells were obtained, the overall effect on shoot regeneration of the two lines was negative. On the other hand, Snyder *et al.* (1999) observed higher transformation efficiency when the *ipt* versus the reporter *gusA* gene was introduced via *Agrobacterium*-mediated gene transfer. They speculated that this may reflect an enhancing effect of cytokinin on regeneration due to expression of the introduced *ipt* gene. Taken together, these results suggest that fine-tuning *ipt* transgene expression in sugar beet cells may be a tool for enhancing regeneration of transgenic plants.

2.5.7 Sucrose accumulation

There is a strong negative correlation between sugar concentration and dry root mass in sugar beet (Hosford *et al.*, 1984), a barrier for increasing sugar beet productivity by conventional breeding methods. High-sugar yield and concentration could potentially be achieved in roots containing more cambial rings with shorter diffusion paths between phloem and accumulating cells (Milford, 1973; Wyse, 1979). Cytokinin and auxin plant growth regulator concentrations are correlated with the formation and expansion of secondary cambia during storage root growth (Hosford *et al.*, 1984). High-cytokinin levels were similarly correlated with cambial initiation and rapid cell division in developing tap roots and just prior to cytokinesis in synchronized tap root cell suspension cultures (Elliott *et al.*, 1984, 1986). Additionally, cytokinins have long been known to modulate assimilate movement in plants and that photosynthate transport increased to the site of cytokinin application. Taken together, these results suggest that higher cytokinin levels may increase cell division, the number of vascular rings and sucrose accumulation in taproots (Monger *et al.*, 1995).

As part of an effort to alter carbohydrate partitioning and activate otherwise dormant supernumerary cambia, which typically contribute little to root growth in *B. vulgaris* (Elliot *et al.*, 1996), sugar beet cells were transformed with the *ipt* gene. Expression of the *ipt* gene fused to a potato tuber-specific promoter from a class

I patatin gene (*Pat*) in transgenic sugar beet increased zeatin riboside concentrations up to 18-fold in the leaves while a corresponding 2-fold increase was observed in the tap roots (Ivic *et al.*, 2001). Leaf concentrations of major nonstructural carbohydrates, sucrose, glucose, and starch were not significantly altered. Higher sucrose levels were found in young tap roots, however, in mature plants, tap roots were greatly reduced in size and had lower carbohydrate concentrations. It is possible that both high cytokinin and sucrose content in younger plants subsequently had a negative effect on normal tap root development leading to a decrease in sucrose accumulation during later stages of growth. Adjusting the expression of the *ipt* gene with precisely regulated promoters may promote expansion of the cambial rings for increased sucrose accumulation.

2.6 Testing of the Activity and Stability of Inheritance of the Gene and Adverse Effects on Growth, Yield, and Quality

Laboratory and field evaluations of GM herbicide tolerant (GMHT) beets have indicated variability among transformants in terms of transgene expression (Steen *et al.*, 1986; Steen and Pedersen, 1995a; BBA, 2002), but given the insertion of a gene cassette into complex genome, this is not surprising. Early field trials of GMHT beets noted considerable variability in field evaluations of herbicide tolerance to glyphosate as well as in testing of resistance to BYNVV using a CP gene (Steen and Pedersen, 1993, 1995a; Tenning *et al.*, 1995). Some of the variance was ascribed to position effects based on the area of the genome where transgenes had inserted, however, evidence of breaks or crossovers were not uncommon (Pedersen and Steen, 1995; Steen and Pedersen, 1995b); this phenomenon is in no way unique to sugar beet.

Variation in insertion number and environmental influences were noted with respect to glyphosate tolerance, however, ploidy effects and the number of insertions did not appear to correlate with or influence observed tolerance to the herbicide. Gene silencing due to methylation of transgenes and post-translational mechanisms also likely played a role in observed variation of transformants evaluated in the greenhouse

and field. In some instances, adequate transgene expression in the greenhouse-screening protocols was lost or reduced in field evaluations. Alterations in morphological and physiological characters not associated with the transgenes were noted, but were generally rare among GMHT beet plants tested in the field for herbicide tolerance. Field trials in Denmark, France, England, and the United States in the early 1990s did not indicate any association between the presence of a transgene for glyphosate tolerance and alterations in root yield, sugar yield, polarization, or juice purity (Steen and Pedersen, 1995a). That is, while there were evidences of a yield enhancement from increased weed control, the transgene itself did not result in a significant metabolic cost or yield drag on the lines evaluated.

One of the early Roundup Ready beet lines submitted for approval of commercial use, Monsanto and Syngenta's GTSB 77, contained a stable insertion of a single copy of the *cp4 epsps* and *gusA* genes, however, the *gox* gene was found to be truncated during insertion and not capable of acting as a template for protein expression (FDA, 1998a). The line was eventually deregulated by the United States Department's Animal and Plant Health Inspection Service Agriculture (USDA-APHIS) for commercial use, but withdrawn from further consideration for approval by the European Union (EU), presumably due to questions with the remaining 69% of the *gox* gene present, but nonexpressed, in this line. It was never released commercially in the United States either despite the deregulation status obtained in 1999 (FR, 1999).

The more recently deregulated GMHT beet line approved for commercial use in the United States and Canada, H7-1, contains a single insertion of the *epsps* gene and does not contain the *gox* or *gusA* genes. Inheritance and gene expression with this line have proven to be stable and predictable (CFIA, 2005; FR, 2005). This sugar beet line (or any other GM beet) has not been approved for commercial cultivation in the EU as of this writing, but is awaiting food and feed approval. Compositional analyses of the H7-1 GMHT beet plants indicated that when comparing H7-1 to nontransgenic control plants, no differences were observed for ash, crude fiber, crude protein, dry matter, soluble carbohydrates, saponins, crude fat, acid detergent fiber, and neutral detergent fiber.

Processed sugar beet (brei) was also analyzed for sucrose, sodium, potassium, amino nitrogen, and invert sugar levels with none of the values exceeding the literature ranges for sugar beet (FDA, 1998a).

As sugar beets are selected in the course of a breeding scheme for agronomic characteristics and specifically for appropriate expression of the transgene(s), many individual transformants with varying copy number of insertions and possibly deleterious effects from tissue culture, have been rouged out of the population. Hence, the lines promulgated for experimental field trials are reasonably well characterized, predictable, and agronomically suitable. As regulatory authorities examine inheritance and stability of gene expression at this stage, most of the unwanted variability has been selected out and transgenes are typically single copy inserts which follow predicted Mendelian inheritance patterns (FR, 1998, 2005; CFIA, 2005).

3. FUTURE ROAD MAP

3.1 Expected Products

3.1.1 Disease resistance

Wider acceptance of transgenic technology within the sugar beet community will pave the way for the introduction of transgenic beets with improved defenses. The genetic base of the commercial sugar beet crop is quite narrow; the early beet sugar industry was based upon a few open-pollinated lines that had been selected for high sugar concentration. Additionally, heritability of some resistances is low and breeding efforts often come at the expense of other agronomic traits. Transgenic technology will allow for the introduction of foreign resistance genes to create new, more durable sources of resistance. In many instances, plants recognize invading pathogens through a gene-for-gene interaction in which a plant R gene (receptor) recognizes a pathogen avirulence (*Avr*) gene (effector) that activates downstream defense responses (DeFeyter *et al.*, 1993; Romeis *et al.*, 1999). Transfer of receptors using transgenic technology has been an effective means of generating new sources of resistance in crops. However, there are conflicting reports of

how well plant R genes function when transferred between plant families. The flax genes *L2*, *L6*, and *L10*, which confer resistance to *Melampsora lini* were transferred to tobacco. Only one allele, when overexpressed, had efficacy against tobacco pathogens. However, the resistance was broad spectrum and effective against *Cercospora nicotianae* and *Phytophthora parasitica* (Frost *et al.*, 2004). This is similar to an observation that a resistance gene from common bean conferring resistance to bean dwarf mosaic virus, when transferred to tobacco provided resistance to CaMV (Seo *et al.*, 2006). Both instances suggest some receptors have broad-range efficacy and function in diverse plant families. In contrast, *Bs2* from pepper, which confers resistance to *Xanthomonas campestris* retains function in solanaceous plants, but is nonfunctional in other families suggesting that some R gene functions are taxonomically restricted (Tai *et al.*, 1999). Within the same family, overexpression of an identified defense-related gene, *Pto*, in tomato increased resistance against the bacterial pathogen *Pseudomonas syringae* by constitutive activation of plant defense responses in the transgenic lines (Tang *et al.*, 1999).

Transfer of broad-spectrum resistance from other crops could provide a needed alternative for achieving durable levels of resistance in sugar beet. Some sugar beet resistance against the fungal pathogen *Fusarium oxysporum* appears to lack durability and their efficacy varies by geographic location (Linda Hanson, personal communication). Type I resistance against *Fusaria*-causing head blight in cereals, some of which infect sugar beet (i.e., *F. graminearum*, Hanson, 2006) is coded for by a major gene (Steed *et al.*, 2005). This gene would be an ideal candidate for use in transformation, because, currently, there is no resistance against *F. graminearum* in sugar beet. However, since the efficacy of R genes has been shown to be variable in other systems, candidates from other crop systems should also be evaluated including those from corn (Isebaert *et al.*, 2005) and soybean (Iqbal *et al.*, 2005).

Transgenic technology can similarly provide approaches for the transfer of resistance genes between sugar beet varieties to generate lines with resistance to multiple pathogens. Transfer of resistance from wild relatives to cultivated crops has been a successful approach for cereals

(Rubiales *et al.*, 2001). Several wild relatives of sugar beet contain resistance to major sugar beet pathogens. Introgression of these genes through traditional breeding can be very difficult, especially when trying to transfer genes between an annual relative and the biennial cultivated beet. In addition, when cyst nematode resistance from a wild relative (*B. procumbens*) was introgressed into sugar beet, it had a significant negative impact on yield (Schulte *et al.*, 2006). Transfer of the resistance gene through genetic modification may provide a cleaner transfer that does not impart the same deleterious effects. Rhizomania, caused by BNYVV, is a major threat to sugar beet production worldwide. Resistance sources within sugar beet are limited (Lewellen *et al.*, 1987) and appear to be losing efficacy in certain areas. The wild beet *B. vulgaris* subsp. *maritima* contains additional sources of resistance (Gidner *et al.*, 2005) and genetic modification may provide the best avenue for integrating these genes into sugar beet, including possible pyramiding of the R genes. There are great efforts being made to identify novel sources of resistance to a wide array of pathogens in wild beet relatives for future use in sugar beet (Francis and Luterbacher, 2003; Panella and Lewellen, 2006), which may be introduced with transgenic technology.

Lastly, to create novel disease control strategies, transgenic technology can be used to overexpress resistance-associated proteins to increase host resistance. Expression of an allele of tobacco chitinase in strawberry created a new line of defense against gray mold, for which strawberry has no natural lines of defense (Vellicce *et al.*, 2006). Even though chitinase reduced disease severity by approximately 50%, overexpression of two other defense-related proteins, a glucanase and thaumatinlike protein, did not enhance resistance, suggesting that not all proteins induced during the resistance response may be directly responsible for disease control. Furthermore, even though chitinase is associated with antifungal responses, overexpression of the tobacco gene did not confer increased resistance against *Colletotrichum acutatum*, suggesting some pathogen specificity of the chitinase alleles. Transfer of a defense-related protein from pepper to *Arabidopsis* created transgenic lines with accelerated growth, and increased tolerance to several biotic and abiotic stresses (Lee and Hwang, 2006). Overexpression of

defense-related proteins never provides complete immunity against invading pathogens, therefore, transformation of lines with existing resistance capabilities may result in greater efficacy of the overall defense response.

Several researchers are investigating key components induced in sugar beet in defense against an array of different pests and pathogens, including: sugar beet root maggot (Puthoff and Smigocki, 2007), *C. beticola* (Nielsen *et al.*, 1997; Lee Panella, personal communication), *R. solani* (Nagendran and McGrath, 2006), BNYVV, and *F. oxysporum* (Larson *et al.*, 2007). Cross-comparisons between resistance responses of sugar beet to several pests and pathogens will allow for selection of a wide array of resistance-associated genes that can be manipulated in hopes of developing broad-spectrum resistance in transgenic sugar beet.

3.1.2 Insect resistance

Cytokinins are known to influence numerous physiological and biochemical plant processes as well as plant defense responses. Cytokinin applications have been correlated with the subsequent accumulation of secondary metabolites, many of which are known to be insecticidal (Hallahan *et al.*, 1992; Decendit *et al.*, 1992; Chilton, 1997). In field trials, an overall increase in yields was attributed in part to reduced insect populations which were correlated with the concomitant accumulation of four secondary metabolites with known insecticidal properties (Hedin *et al.*, 1988; Hedin and McCarty, 1994). To specifically focus on the effects of elevated cytokinin levels on insect resistance, the *ipt* gene was fused to a wound-inducible promoter for expression in transgenic plants (Smigocki *et al.*, 1993; Smigocki, 1995). The 70-fold higher cytokinin levels in late-flowering *Nicotiana* were correlated with resistance to a number of insects (Smigocki *et al.*, 1993). Insecticidal activity was localized primarily to leaf surfaces that upon chemical analysis revealed compounds suggestive of oxygen-containing aliphatic molecules in the molecular weight range of diterpenes (Smigocki *et al.*, 1997, 2000). These *Nicotiana* compounds killed almost all SBRM larvae, a major sugar beet pest in the central and western United States and Canada. These results suggest that cytokinin-mediated

insect resistance could potentially provide effective SBRM control.

Assimilation of dietary nutrients and proteins from ingested plant tissues is critical to insect survival. Inhibition of digestive proteases, therefore, is yet another potential target for development of effective strategies for insect control. Digestive proteinase inhibitors (PI) are enzymes that occur naturally in many plants (Jongsma and Bolter, 1997; Christeller *et al.*, 1998; Haq *et al.*, 2004). PI genes have been cloned, reconstructed and expressed in transgenic plants, and shown to enhance insect or nematode tolerance (Maqbool *et al.*, 2001; Cowgill *et al.*, 2002a, b; Samac and Smigocki, 2003). Several coleopteran pests that commonly use cysteine proteases for protein digestion, as well as nematodes, were inhibited by cysteine PI genes of the oryzacystatin I (*OCl*) and II (*OClI*) PI gene family (Kondo *et al.*, 1990; Michaud *et al.*, 1995; Samac and Smigocki, 2003). Clones of trypsin/serine PIs were shown to specifically enhance resistance to pests that use serine digestive proteases (Heath *et al.*, 1997). A *Nicotiana glauca* gene, post-translationally cleaved into five individual trypsin (serine) PIs, was overexpressed in transgenic plants and effectively targeted insects representing four different insect orders (Charity *et al.*, 2005). Simultaneous overexpression of two classes of PI genes provided resistance to more than one insect in tomato (Abdeen *et al.*, 2005). Similarly, additive effects of a cowpea trypsin inhibitor paired with a pea lectin or a *Bt* gene and of a serine PI gene with a *Bt* gene enhanced resistance to several insects (Boulter *et al.*, 1990; MacIntosh *et al.*, 1990; Zhao, 1996). These studies suggest that pyramiding the expression of PIs with defense genes with different mechanisms of action should provide an advanced strategy in pest management as it should be more effective in overcoming a general adaptive response in the insect. Gene pyramiding is also proving to be useful for addressing the limitations that are being encountered with cultivation of genetically engineered plants, mainly buildup of resistance in the targeted pest or pathogen (Mehlo *et al.*, 2005).

SBRM is the most devastating insect pest of sugar beet in North America. Developing larvae feed on tap and feeder roots throughout the growing season inflicting significant crop damage either by completely severing the roots of seedlings or badly scarring the larger roots (Dregseth *et al.*,

2003). Further damage is inflicted on damaged tap roots by opportunistic pathogens such as *E. betavascularum*, *Aphanomyces cochlioides*, and *R. solani*. *Erwinia* infections alone can reduce sugar yields by as much as 10–15%, not including losses during postharvest storage of the roots. Effective SBRM control measures are lacking (Yun, 1986; Campbell *et al.*, 2000). Two major classes of digestive enzymes were identified as targets for control of the SBRM (Wilhite *et al.*, 2000). They were shown to be effectively blocked by several plant PIs that included a soybean trypsin-chymotrypsin and a squash aspartyl inhibitor. Pyramiding the expression of the corresponding PI genes in sugar beet roots is an approach that may prove effective for enhancing resistance to SBRM. Various PI gene constructs have been introduced into sugar beet hairy roots and are in the process of analysis for insect and disease resistance (Smigocki, 2008).

3.1.3 Defense response genes

Research efforts focused on discovering and characterizing sugar beet root defense responses will lead to the discovery of the underlying genetic and molecular mechanisms controlling resistance. An in-depth understanding of molecular basis of interactions between arthropods and plants is crucial for development of novel control strategies for invasive and re-emerging pests that are not dependent on environmentally persistent and damaging pesticides (see reviews Stotz *et al.*, 1999; Baldwin *et al.*, 2001; Kaloshian, 2004; Kaloshian and Walling, 2005). Studies on root responses to insect attack are less represented primarily due to the limitations imposed by the complexity of the rhizosphere environment (Wu *et al.*, 1999; Bird and Kaloshian, 2003; Puthoff *et al.*, 2003; Williamson and Gleason, 2003; Bird, 2004). Sugar beet and SBRM are being utilized as a model system for studying the molecular aspects of root–insect interactions and to gain knowledge of root resistance mechanisms (Puthoff and Smigocki, 2005, 2007). Profiling of genes whose expression is modulated by insect feeding has been primarily studied utilizing *Arabidopsis* gene chips, and only a few studies examined the transcriptional profiles induced in the insect's natural host (Hui *et al.*, 2003; Puthoff *et al.*,

2005; Wang *et al.*, 2005). In each of these studies, specifically up-regulated genes were identified in a pool of responsive genes.

Expressed sequence tag (EST) libraries enriched for genes involved in the initial responses of sugar beet roots to insect herbivory were generated from a breeding line showing moderate resistance to SBRM and from a susceptible line (Puthoff and Smigocki, 2007). Many of the identified genes were found to be regulated by other pathogens including insect pests. These included a polyphenol oxidase gene (Voelckel and Baldwin, 2004), a β -glucosidase gene (van de Ven *et al.*, 2000), a glutathione S transferase gene (Reymond *et al.*, 2000), a subtilisinlike serine protease gene (Tornero *et al.*, 1996), and osmotinlike protein gene (Zhu *et al.*, 1995). In addition, regulation of pathogenesis-related (PR) protein genes was found and included a chitinase gene, oxalate oxidaselike genes, peroxidase genes, osmotinlike genes, and a PR10-like gene. While PR protein genes are typically induced after microbe infections they have also been found to be regulated by insect feeding (Hui *et al.*, 2003; Voelckel and Baldwin, 2004). Only a single gene coding for a PI with similarity to serine PIs was cloned from the moderately resistant line. Interestingly, since serine protease activity has been shown to be one of the major activities in SBRM larval guts (Wilhite *et al.*, 2000), these results strongly suggests that it may play a role in resistance and warrants further investigation (Smigocki, 2008). The identification of genes following SBRM larval feeding on moderately resistant varieties allows for the formulation of testable hypotheses to gain knowledge on root defense responses and the mechanism of resistance. This valuable information will lead to development of alternate control measures based on biotechnological approaches thus providing new tools to breeders that will ultimately broaden pest and disease resistance of sugar beet and be more generally applicable to other crops and diseases.

3.1.4 Sucrose accumulation

In order to enhance storage and utilization of sucrose in the tap root, an understanding of basic mechanisms controlling the metabolism of carbon in sugar beet is needed. A plant SNF-1

(sucrose nonfermenting-1, SnRK1) protein kinase has been shown to play a central role in the signal transduction pathway linking the perception of cellular glucose levels with the derepression of a range of glucose-repressible genes (Monger *et al.*, 1997; Purcell *et al.*, 1998; Schwachtje *et al.*, 2006). It has been demonstrated in transgenic potato that expression of an antisense *SnRK1*-related sequence decreased sucrose synthase gene expression and eliminated sucrose inducibility of the sucrose synthase enzyme. SnRK1 protein kinases have also been implicated in regulation of other important metabolic enzymes, among them nitrate reductase that affects assimilation of nitrogen into amino acids and sucrose phosphate synthase, the most important enzyme for sucrose synthesis in plants (Halford and Hardie, 1998). Taken together, these findings strongly implicate a role for the SnRK1 enzyme as a significant regulator of carbohydrate metabolism that may be exploited to increase sucrose storage and accumulation in sugar beet (Purcell *et al.*, 1998). Interestingly, Schwachtje *et al.* (2006) recently demonstrated that antisense suppression of SnRK1 in *N. attenuata* transgenic plants altered resource allocation to the roots. Transgenic plants were more tolerant to insect attack, suggesting that this tolerance mechanism complements the likely defensive value of diverting resources to a less vulnerable location within the plant.

3.1.5 Synthesis of novel starches

Preliminary research regarding starch synthesis in sugar beet is being addressed (Monger *et al.*, 1995). Even though starch is transiently made in sugar beet leaves, no starch accumulates in the roots of any *Beta* species. Understanding starch synthesis in sugar beet may enable novel types of starches suitable for industrial purposes to be made. This would provide yet another alternative role for producing value added products in sugar beet.

3.1.6 Biofuels

Due to its high productivity, sugar beet is becoming increasingly interesting not only as a source of sugar, but also as a possible “green

bioreactor”, i.e., for synthesis and accumulation of new metabolites in roots (Sévenier *et al.*, 1998; Menzel *et al.*, 2003). Reports at the Third Annual World Congress on Industrial Biotechnology and Bioprocessing indicated that industrial technology is expected to account for about 10% (\$125 billion in value) of sales within the chemical industry (Agricultural and Environmental Biotechnology Conference, Melbourne, Australia, 2006). Much of the projected growth is expected to come from industrial biotechnology that includes products made from bio-based feedstocks or through fermentation or enzymatic conversion. Biofuels such as ethanol and biodiesel will significantly contribute to the growth. Currently, the production of biofuels is not cost effective because more energy appears to be required to produce alcohols (ethanol, butanol, methanol) from sugar beet than can be extracted from it. However, with the application of biotechnology, higher conversion technology at a lower cost is anticipated to allow for broader commercialization with meaningful production rates.

3.2 Addressing Risks and Concerns

Field trials of GMHT sugar beet have been conducted since 1990 in Europe and shortly thereafter in the United States; however, concerns over consumer acceptance of sugar in human foods and pulp products and molasses as feed has led most sugar processors to forego the technology and agronomic enhancements offered (Bennet *et al.*, 2004). While the sucrose produced from processing GMHT sugar beet cannot be differentiated with sensitive diagnostic tests from that produced by organic or conventionally cropped beets, the EU and Japan both mandate that sugar from sugar beets be labeled as GM (EP, 2003; MAFF, 2006), however, the processed molasses and sucrose will not require labeling for Japan (BSDF, 2006; FAS, 2006). Japan, the EU, and other countries have previously raised concerns over importation of sugar beet pulp derived from GM beet, but progress in resolving these issues continues to evolve. Still, despite the lack of detectable DNA or protein associated with this genetic modification in processed sucrose and pulp or molasses products (Klein *et al.*, 1998; FSANZ, 2006), EU directives will require labeling

of all foods that may contain products derived from GM beets. In accord with the Japanese ruling, the Australian and New Zealand Food Standards agency has required that only materials derived from GM beet, which indicate the detectable presence of GM protein or DNA, need to be labeled. Hence, molasses, sugar, and pulp wherein the DNA or protein cannot be detected do not require special labeling procedures (FSANZ, 2004).

With respect to risk assessment and management of GMHT sugar beet, there is a startling contrast in approach between the EU and US regulatory systems with respect to weed management and environmental considerations. The Farm Scale Evaluations (FSE) conducted in the United Kingdom, which considered GMHT beet, potato, and oilseed rape as comparators to their nonengineered counterparts, assessed the impacts of weed management (i.e., decline in weed type and number) on wildlife associated with the agroecosystem (Heard *et al.*, 2003; Squire *et al.*, 2003). While the FSE compared GMHT beet to nontransgenic controls over a substantial growing area, the real comparator was weed control and not the transgene directly. That is, a decrease in weeds and the ensuing effects (e.g., availability of seeds for granivorous birds and insects, biodiversity within agricultural fields) may well be attributed to any mechanism (e.g., cultivation, traditional chemical herbicides, planting dates, etc.), which controls weed populations regardless of the mode of action. A resultant measure stemming from the FSE is the introduction of cropping schemes wherein a small percentage (e.g., 5%) of the GMHT beet field is intended not to receive glyphosate or glufosinate applications as a means of maintaining a food source for birds and other wildlife. It is not clear if effects of traditional herbicide regimes were previously evaluated for their impacts on wildlife prior to the advent of GM technology or if new chemical herbicides will undergo the same scrutiny in the EU system as GMHT crops.

In contrast to this situation in the EU, in the United States, herbicides are registered under the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA) by the US Environmental Protection Agency (US EPA) with the expectation that efficacy in weed control may result in an absence of weeds throughout an agricultural field. FIFRA is a cost:benefit statute, which relies on a standard

of no significant adverse environmental effect in decision making relative to pesticide registration. As such, use of broad-spectrum herbicides like glufosinate and glyphosate are expected, even intended, to result in a relatively clear field with respect to weed population numbers. This difference may be in part a result of differing perspectives on what constitutes “nature” or wild lands between the EU and the United States (Madsen *et al.*, 2005).

Another dichotomy noted between the EU and United States regards the issue of coexistence of crop types that are engineered with those intended to be GM free (i.e., organically cultivated). The USDA’s National Organic Program (NOP) is process based, meaning that if all aspects of planting, cultivation, and harvest were performed according to a NOP certified organic program, the resulting produce derived may be labeled as organic despite the possible presence of GM traits from wind or insect vectored pollen. There is currently no organic sugar production in the United States to speak of, but this is not the case in the EU and other countries. The EU has established separation distances for GM beet of 1.5 m from conventional beet and 3.0 m from certified GM-free beet (i.e., organic) or seed production fields. This distance is established with the expectation that the GM beets will not contain bolters (i.e., flowering plants) as a source of pollen and the GM-free beets will similarly not contain flowering beets.

Gene flow from commercial beet plantings to weed beets (e.g., *B. vulgaris* ssp. *maritima*; *B. macrocarpa*) can be affected by wind-borne pollen over distances of at least a few kilometers (Boudry *et al.*, 1993; Bartsch and Pohl-Orf, 1996; Bartsch *et al.*, 2002). Weed beets are present in coastal areas in Europe and in portions of sugar beet growing areas of California in the United States. Although most commercial fields and experimental trials with GMHT or rhizomania resistant beet are not likely to contain bolters, nevertheless, there are occasions when pollen may be exchanged in either direction between *B. vulgaris* ssp. *vulgaris* and weed beets with the expression of transgenes in the hybrid progeny (BBA, 2002).

While the presence of a transgene expressing an herbicide tolerance mechanism in a weed beet appears to offer little or no selective advantage to the recipients of this trait in the absence of

herbicidal treatment, the establishment of feral or ruderal beets with herbicide tolerance can lead to weediness issues in subsequent crops including beets (Bartsch *et al.*, 2002). Additionally, flowering weed beets or chard present in seed production areas can contribute to genetic stock used in cultivar development. Sequential cropping with Roundup Ready and Liberty Link crops may further select for resistant weed type beets. Those with an annual habit may exacerbate this issue as they continue to flower in field wherein commercial beets typically would not. Due in part to this situation, applicants to the EU have agreed to follow a stewardship plan in which deployment of GMHT beet and other HT crops are managed and monitored so that selection of weeds for herbicide tolerance are precluded or minimized (Bartsch *et al.*, 2002; EFSA, 2006).

While these types of stewardship and monitoring plans may not be a formal part of the requirements stemming from deregulation of GMHT beets or the labeling amendments for the herbicides applied to HT crops in the United States, applicants for deregulation will be monitoring for development of herbicide-tolerant weeds within the agroecosystem. As Bartsch *et al.* (2002) point out, the EU comprehension of nature conservation includes agricultural areas. This again may explain in part the differences in regulation and assessment present in the EU and the US relative to GM crops.

3.3 Expected Technologies

3.3.1 Tissue-specific promoters

Transformation technology is evolving at a rapid pace. Not only is the transformation efficiency increasing, but the timing and tissue specificity of expression can be controlled by using specialized promoters thus minimizing the possible negative effects that may be associated with constitutive transgene expression in engineered plants. In sugar beet, several tissue specific promoters have been characterized that include the chlorophyll a/b binding protein promoter for high level of leaf-specific expression (Stahl *et al.*, 2004) and several root-specific promoters showing either restricted expression in the vascular tissue or throughout the root (Oltmanns *et al.*, 2006). Additional source

of root-specific gene promoters was identified when clones derived from a root-specific EST library were analyzed for expression patterns in various root tissues (Smigocki, unpublished results). Heterologous promoters are also useful for expressing beneficial genes in sugar beet. A *Medicago truncatula* root-specific promoter from gene *MtHP*, which shares sequence similarity to PR10 multigene family (Xiao *et al.*, 2005) was shown to be constitutively expressed at high levels in sugar beet hairy roots and may prove to be a useful alternative to the 35S promoter for high levels of constitutive expression in roots of transformed plants (Figure 1e; Smigocki, unpublished results). Tissue-specific promoters are highly desirable for maximizing expression at site of interest and will be effective for targeting beneficial transgene expression to tissues most prone to insect and pathogen attack and for manipulating sucrose production in sugar beet roots.

3.3.2 Inducible promoters

As mentioned above, constitutive overexpression of some genes can have detrimental effects on plant growth and development. Some genes need only be induced at certain stages in growth. Tighter control of gene expression will be achieved by using inducible promoters. Using a promoter from a heat-shock protein allows for heat-induced gene expression in *Arabidopsis* (Masclaux *et al.*, 2004). This system requires incubation at high temperatures with high humidity and has worked better with *in vitro* cultures than mature plants, which would be more suited for laboratory studies rather than large-scale field production. Several chemical inducible promoters are also available including those activated by application of tetracycline, dexamethason, copper, tebufenozide, oestrogen, and ethanol (Moore *et al.*, 2006). Accumulation of hexoses at the expense of sucrose in beet taproots during storage is caused by invertase activity (Rosenkranz *et al.*, 2001). Additionally, the concentration in sugar beet tap roots is negatively affected by sucrose synthase activity (Klotz and Campbell, 2004). The potential use of inducible promoters to produce inhibitors of these enzymes during storage could be of substantial benefit to sugar beet processors since upwards of 250 g of sucrose is lost per ton

per day while the roots are held in storage, in some cases for longer than 200 days.

3.3.3 Excision of antibiotic resistance

Antibiotic resistance as a means of selection has been a staple tool in the development of transgenic organisms. However, antibiotic resistance is not desired in the final product. It raises concerns about gene flow to soil and gastrointestinal microorganisms and weeds within the neighboring fields. Elimination of the selectable marker may increase the willingness of the public to accept transgenics. Several methods widely employed in the past were time consuming and transformation process dependent, therefore, the procedures were not widely applicable across plant species. Recently a chemical-inducible DNA excision system was developed that allows for site-specific excision of marker sequences (Zuo *et al.*, 2001). With this system, treatment with β -estradiol activates transcription of a Cre recombinase. This enzyme excises the unwanted sequence through recombination using the *loxP* sites that flank the ends of the selectable marker coding region (Dale and Ow, 1991) and now the selectable marker and *cre* coding sequence as well (Zuo *et al.*, 2001). This approach has been successful in *Arabidopsis* (Zuo *et al.*, 2001), rice (Sreekala *et al.*, 2005), and tomato (Zhang *et al.*, 2006).

3.3.4 Virus-based gene vectors

Plants provide cost-effective platforms for production of therapeutics or other value added products. A limiting factor for this approach has been the inability to produce large quantities of the product in plants. Most recently, Giritch *et al.* (2006) demonstrated that the production of heavy and light chains of the human IgG antibody was expressed in 85% versus 5% of the *N. benthamiana* cells if each gene (i.e., one for heavy and one for light chain) was expressed on two different viral plant vectors (tobacco mosaic virus and potato virus X). The overall yield of the protein product was increased 10-fold using this dual-vector system. Similar approach can be explored in sugar beet for production of value added products using, for example, the beet mosaic virus

(BtMV). BtMV is a member of the economically important potyvirus group of plant viruses that infects sugar beet and its close relatives. It is distributed worldwide in all major beet-growing areas and, in mixed infections with certain other viruses, causes severe stunting and yield losses on susceptible sugar beet varieties. The complete nucleotide sequence of BtMV genomic RNA has been determined and will facilitate accurate diagnosis and differentiation of the virus as well as development of virus resistant plants (Nemchinov *et al.*, 2004). In addition, the BtMV virus can be engineered to transiently express useful proteins of interest in sugar beet. Production in sugar beet of effective biomedical products for control of human and animal diseases, as well as other useful products, should provide an environmentally friendly and relatively inexpensive approach for production of new and raw materials.

3.4 Specific Regulatory Measures

Within the United States' Coordinated Framework for Regulating Biotechnology (<http://usbiotechreg.nbii.gov>), three agencies have principal authority and oversight for experimentation, culture, and food or feed production involving transgenic sugar beets. USDA-APHIS performs environmental assessments for genetically engineered crops like sugar beet under authority of the National Environmental Policy Act and the Plant Protection Act. USDA-APHIS has performed an environmental assessment on both Roundup Ready and Liberty Link sugar beets, reaching a finding of no significant impact in both instances. Both Roundup Ready sugar beet (FR, 1999, 2005) and Liberty Link sugar beet (FR, 1998) have been deregulated by the agency, meaning that they are cleared for commercial purposes to be cultivated without further regulation by the USDA. The Monsanto beet line GTBS77 was deregulated in 1999, but has not been commercially cultivated (Russell P. Schneider, Monsanto Company, personal communication). Line H7-1 has recently been approved by the agency for commercial use (FR, 2005).

Approval has been granted by the US EPA under FIFRA to amend the pesticide labels for glyphosate and glufosinate so that they may be applied to GMHT sugar beets. As part of

this process, the US EPA has also performed an analysis to determine that a food and feed tolerance has been granted for herbicide residues that may exist on plant materials derived from these GMHT beets under the Federal Food, Drug and Cosmetic Act (FFDCA).

Voluntary consultations with the Food and Drug Administration (FDA) have also been conducted for the use of the herbicide tolerance mechanisms (e.g., EPSPS, PAT proteins) resulting from the genetic modifications of Roundup Ready beets (FDA, 1998a, 2004) and Liberty Link (FDA, 1998b) sugar beets. The FDA consultation reviews the similarity of the GMHT beet to conventional beet cultivars to determine if the genetically engineered line has significantly altered nutritional or biochemical constitution. Given the use of these herbicide resistance mechanisms in other crops previously, it is not surprising that FDA did not find any cause for concern with respect to food or feed safety from using GMHT beet.

In 2006, Roundup Ready beets were grown on approximately 250 acres in the United States and will be processed through a standard processing plant in the spring of 2007 (BSDF, 2006). A similarly sized acreage of Roundup Ready beets will be cultivated in the United States in 2007 and again processed through a standard sugar beet processing facility with segregation of products such that study and distribution may proceed. Larger acreages of Roundup Ready beets are planned for 2008 in the United States. The situation and progress in the EU are less clear.

In a similar finding, the Canadian Food Inspection Agency has approved Roundup Ready sugar beet for unconfined environmental release and use as livestock feed (CFIA, 2005). Health Canada has separately reached a conclusion of safety for food uses of Roundup Ready sugar beet (HC, 2005).

Several field trials with GM beet expressing resistance to BNYVV have been conducted in the United States, Sweden, Denmark, France, the United Kingdom, Spain, Greece, Iran, and other countries under various regulatory authorities and guidelines. Regulatory variances among countries and even within a country or collective regulatory body (e.g., EU/EC) have had an impact on the development and deployment of GM technology in sugar beet. Following legal changes stemming from political influences, sugar beet variety trials

with GM beet in the EU were abandoned in 2000 (Märländer, 2005). Subsequently, the glufosinate-tolerant beet was removed from official application for consideration of market access.

The US EPA is currently revising its policies regarding registration of plants expressing viral CPs for resistance to viral infection. It is not clear at this juncture if the BNYVV-resistant sugar beet lines field tested for suitability will need to undergo a full registration process prior to approval for commercial release or meet established exemption criteria. Previous viral-resistant plants were assessed through the USDA-APHIS and were considered as exempt by US EPA from the requirement of a food tolerance action under FFDCA without the need for FIFRA Section 3 registration, so US EPA action on these products was minimal. That may well change as new measures are instituted in 2007. This action could seriously impact the timing of deployment of BNYVV and other virus resistant sugar beets in the United States.

Differences inherent in the statutory mandates and in guideline tests required for approval of field releases and food/feed use require significantly more time to satisfy on a country-by-country basis with the lack of regulatory harmonization. Although the US EPA, USDA-APHIS, Canada's CFIA and Health agency, Organization of Economic Cooperation and Development (OECD), and others strive to unify the requirements for commercial application of this technology, on a global scale, relatively little progress has been made. In addition to adding cost to the process, these differences lend themselves to fostering a lack of confidence in regulatory officials and managers making decisions about environmental and health issues. This, in part, may explain much of the dichotomy between the EU and the United States with respect to GM approvals of beet and other crops (FR, 2004; DeVuyst and Wachenheim, 2005; Madsen *et al.*, 2005).

1. INTRODUCTION

The worldwide demand for high-potency sweeteners is expected to increase. With the new practice of blending different sweeteners, the demand for alternatives is expected to increase. The sweet herb of Paraguay, *Stevia rebaudiana* Bertoni, produces in its leaves just such an alternative with the added advantage that stevia sweeteners are natural plant products. In addition, the sweet steviol glycosides have functional and sensory properties superior to those of many other high-potency sweeteners. Stevia is likely to become a major source of high-potency sweetener for the growing natural food market in the future. The task at hand is to convert stevia from a wild plant to a commercial crop well suited to efficient mechanized production. The necessary steps are the development of seed, seedling, and crop production system, including information on optimized crop inputs, weed and disease control, harvest and handling methods, and a breeding program aimed at optimizing glycoside content and sensory characteristics. Understanding the biology of the stevia plants and the chemistry of the sweet glycosides together with application of biotechnology techniques are prerequisites for conversion of stevia to a commercial crop.

1.1 History, Origin, and Distribution

Stevia is a small bush native to the valley of the Rio Monday in highlands of Paraguay, between 25°

and 26° South latitude, where it grows in sandy soils near streams (Katayama *et al.*, 1976). The leaves have been traditionally used for hundreds of years in Paraguay and Brazil to sweeten local teas, medicines, and as a “sweet treat”. Dr M.S. Bertoni botanically described and named the plant in 1905 in honor of Paraguayan chemist Dr Ovidio Rebaudi while “stevia” was adopted from the name of Dr Peter James Esteve (a Spanish botanist) who died in 1566. Stevia is one of the 950 genera of the Compositae (Asteraceae) family. There are now more than 154 *Stevia* species but *S. rebaudiana* is the only one species with significant sweetening properties due to sweet steviol glycosides (Robinson, 1930; Soejarto *et al.*, 1982, 1983); other species do contain other biochemicals of interest. The first reports of commercial cultivation in Paraguay were in 1964 (Katayama *et al.*, 1976; Lewis, 1992). A large effort aimed at establishing stevia as a crop in Japan was begun in 1968. Since then, stevia has been introduced as a crop in a number of countries including Brazil, Korea, Mexico, the United States, Indonesia, Tanzania, and since 1990 Canada (Shock, 1982; Goenadi, 1983; Brandle and Rosa, 1992; Fors, 1995). The species of stevia are found in the wild in semiarid habitats ranging from grassland to mountain terrain.

For nearly 20 years, millions of consumers in Japan and Brazil, where stevia is approved as a food additive, have been using stevia extracts as safe, natural, and noncaloric sweeteners. Japan is the largest consumer of stevia leaves and extracts

(steviosides) in the world, and there it is used to sweeten everything from soy sauce to pickles, confections, and soft drinks. Even multinational giants like Coca-Cola and Beatrice Foods use stevia extracts to sweeten foods (as a replacement for NutraSweet and saccharin) for sale in Japan, Brazil, and other countries where it is approved as a food additive. Other countries use lesser quantities of steviosides. Steviosides have zero calorie and can be used wherever sugar is used, including in baking, etc. They are ideal for diabetic and low-calorie diets; in Japan “Diet Coke” uses steviosides.

Currently, stevia production is centered in China and the major market is in Japan (Kinghorn and Soejarto, 1985). No large-scale mechanized production has been established and stevia sweeteners are not yet found in mainstream food products in most countries of the world. Progress toward large-scale commercialization has been slow, largely due to difficulties in producing the crop, the poor quality of stevia extracts, and the absence of regulatory approvals essential for stevia sweeteners in the North American and European markets.

Both the sweetener and the stevia plant *S. rebaudiana* Bertoni (also known as *Eupatorium rebaudianum* Bertoni) are known and pronounced as “stevia” in English-speaking countries as well as in France, Germany, Italy, Portugal, and Sweden; although some other countries use different names. Similar pronunciations occur in Japan (“sutebia” in Katakana), and in Thailand (“satiwia”). In some countries, India, for example, the name translates literally as “sweet leaf”. Below are some names for the stevia plant in various regions of the world:

- China: *Tian ju*—sweet flower and *Tian ju ye*—stevia leaf.
- English-speaking countries: candy leaf, sugar leaf, sweetleaf (the United States), sweet honey leaf (Australia), and sweet herb of Paraguay.
- German-speaking countries (also Switzerland): *Süßkraut*, *Süßblatt*, and *Honigkraut*.
- India: *Madhu Parani* (Marathi), *Madhu Patra* (Sanskrit), *Seeni Tulsi* (Tamil), and *Madhu Patri* (Telugu).
- Italy: *Piccolo arbusto con foglia dolce*.
- Japan: *Amaha sutebia*.

- Portuguese-speaking countries: *Capim doce*, *Erva doce*, *Estêvia* (Brazil), and *Folhas da stêvia*.
- Spanish-speaking countries: *Caá-ché*, *Hierba dulce*, *Ka’a he’ê* (Guaraníes—natives of Paraguay), *Stevia del norte de Paraguay*, and *Yerba dulce*.
- Thailand: *Satiwia* (*Ya wan*—Bangkok).

1.2 Botanical Description

Stevia is a member of the Compositae (Asteraceae) family (Gentry, 1996). It is a small shrubby perennial growing up to 65 cm in height, with sessile, oppositely arranged lanceolate to oblanceolate leaves, serrated above the middle. Trichome structures on the leaf surface are of two distinct sizes, one large (4–5 μm) and one small (2.5 μm) (Shaffert and Chetobar, 1994). The flowers are small (7–15 mm), white, and arranged in an irregular cyme. The seed is an achene with a feathery pappus (Robinson, 1930).

Stevia is an obligate short-day plant with a critical day length of about 13 h. Extensive variability within populations for day-length sensitivity has been reported (Valio and Rocha, 1966; Zaidan *et al.*, 1980). Plants can initiate flowering after a minimum of four true leaves have been produced (Carneiro, 1990). The reproductive anatomy of the male and female gametophytes is typical for angiosperms (Shaffert and Chetobar, 1992, 1994). Stevia is diploid and has 11 chromosome pairs ($2n = x = 22$), with regular karyotype. This is characteristic of most of the South American members of the genus (Frederico *et al.*, 1996), and reported widely. However, numbers of $2n = 24, 33, 34, 44, 48, 66$, and 70 have also been observed (Darlington and Wylie, 1955; Bolkhoviskikh *et al.*, 1969; Moore, 1973, 1974, 1977; Golblatt, 1981, 1984, 1985, 1988; Golblatt and Johnson, 1990, 1991, 1996, 1998). Recent studies from Oliveira *et al.* (2004) have also confirmed the chromosome number of $2n = 22$ previously reported by Frederico *et al.* (1996) and Monteiro (1980, 1982).

1.3 Economic Importance

The natural habitat of stevia is semihumid subtropics on the Tropic of Capricorn (22–23° South latitude), 200–400 m above the sea level,

with 1500–1800 mm of rainfall and temperature extremes of -6°C to 43°C . It naturally grows in low-lying areas on poor sandy, acidic soils adjacent to swamps, and so is adapted to and requires constantly wet feet or shallow water tables (Shock, 1982; Colombus, 1997; Oddone, 1999). Under cultivation and on more fertile soils, the mature plant can be larger, up to 1.8 m with up to 20 branches per plant (Jia, 1984). Vegetative growth is reduced when temperatures are below 20°C and when day length is less than 12 h. Increasing day length to 16 h and increasing light intensity can increase vegetative growth and stevioside levels (Metivier and Viana, 1979; Yermakov and Kochetov, 1996). Flowering is photoperiod dependent and is enhanced by reducing day length and short-day length. Responses of flowering, and also stevioside content, to day length appear to be variable with some eight cultivars/selections being obligate short-day plants (Brandle *et al.*, 1998); however, some lines appear to be photoperiod insensitive. Stevia has been successfully taken to a wide range of climatic locations around the world and apparently grown successfully, although often by using vegetative propagation methods and seedling establishment in a greenhouse before planting in the field. The typical agronomic research locations have been listed from Russia, Ukraine, North China, Canada, Georgia, California, Korea-Suweon, central China, Japan, Mexico, Taiwan, Thailand, India, Brazil, and Paraguay (Shock, 1982; Goenadi, 1987; Shu, 1989; Gvasaliya *et al.*, 1990; Matejka, 1992; Shyu *et al.*, 1994; Fors, 1995; Chalapathi *et al.*, 1997; Colombus, 1997; Dzyuba, 1998; Oddone, 1999).

Shading has been shown to reduce growth (Slamet and Tahardi, 1988), though factors other than latitude and solar radiation usually limit production. Humidity is reported to be important at some locations as the plant has poor tolerance to water stress; it often visibly wilts under hot, dry conditions even with good soil moisture levels. Rainfall in many locations is supplemented by irrigation to avoid any moisture stress. Only in the more humid and wet areas, rainfall may alone be sufficient for adequate growth for commercial production.

Climatic requirements, of day length and temperature, are different for maximum vegetative production and for maximum flowering and seed production. Soils of the natural habitat are

generally low-fertility, acidic sands (pH 4–5) with shallow water tables and little organic matter, where plants grow to 0.6–0.7 m in height. Under cultivation on better, more fertile soils, growth can increase up to 1.0 m and even up to 1.8 m (Jia, 1984). Soils should be well drained but with reasonable water-holding capacity and preferably with pH 5–7; alkaline soils should be avoided (Oddone, 1999).

1.3.1 Propagation

In the wild, stevia regenerates from seed, from the rooting of plant stems touching the ground (and trampled into the ground), and from regeneration at the base of the plant (crown division). Seed germination is notably very poor, commonly due to sterile seed. Some plant varieties/selections produce virtually no viable seed due to self-incompatibility.

Under cultivation, stevia can be propagated by seed, tissue culture, and vegetative cuttings (and plant separation). A comparison of these three methods (Tamura *et al.*, 1984) showed neither significant difference in growth nor glycoside content; cuttings showed the least and seed the greatest variation among individual plants in chemical composition.

1.3.1.1 Seed propagation

Establishing stevia crop by using seed is more successful in tropical climates where there is no climatic restriction on the length of the growing season. In northern climates, the shorter growing season necessitates seedling establishment in a glasshouse/greenhouse prior to the growing season. Germination and establishment from seed are often poor and sometimes unsuccessful (Shaffert and Chebotar, 1994). Stevia flowers need to be fertilized by pollen from another plant to produce viable seed. A high density of bees (3–4 hives per hectare) is recommended for good seed production (Oddone, 1999). Harvesting of immature seed may also contribute to poor germination (Colombus, 1997).

Fertile seeds are usually dark colored, whereas sterile seeds are usually pale (Felippe, 1978; Oddone, 1999). Seeds are very small (1000 seeds

weigh 0.3–1.0 g) and as a result seedlings are slow to develop, reaching a size suitable for transplanting to the field at 45–60 days (Colombus, 1997; Brandle *et al.*, 1998; Oddone, 1999). Seeds are usually germinated in a greenhouse where a range of bedding materials have been trialed (Carneiro *et al.*, 1997).

Germination rates vary greatly. It can take 4–6 days to reach two-thirds of the final germination of 62–90% at 25 °C (Carneiro and Guedes, 1992). Germination requires at least 20 °C and often more than 25 °C; light generally increases germination.

1.3.1.2 Vegetative propagation

Significant research efforts have been made toward vegetative propagation including *in vitro* multiplication. Cuttings of new stems and shoots can be propagated successfully (Shock, 1982; Gvasaliya *et al.*, 1990; Nishiyama *et al.*, 1991) and rooting of cuttings can be stimulated, but not always, by use of growth regulators (Zubenko *et al.*, 1991; Carvalho and Zaidan, 1995; Kornilova and Kalashnikova, 1996); some growth regulators can sometimes influence (increase) the concentration of steviolosides in the leaves (Acuna *et al.*, 1997). The size (number of leaves) of cuttings and day length during cutting can influence rooting and growth. Cuttings taken in late winter rooted better than those taken at other times (Carvalho and Zaidan, 1995).

For tissue cultured propagation many different parts of the plant can be used successfully—leaves, auxiliary shoots, root-neck sprouts, shoot primordia, internodal explants, etc. *In vitro* multiplication has been used frequently to multiply individually selected or bred clones and successful procedures have been documented (Handro *et al.*, 1977; Ferreira and Handro, 1988a, b; Carneiro *et al.*, 1992; Kornilova and Kalashnikova, 1996; Uddin *et al.*, 2006).

1.3.2 Economic attributes and industrial uses

Stevia products are known to be used as artificial low-calorie (nonsucrose) sweeteners and for most other purposes where sugar can be used. The primary use is as a sweetener to enhance the

palatability of foods and drinks. Unlike aspartame, stevia sweeteners are heat stable to 200 °C, are acid stable, and do not ferment, which makes them suitable for use in a wide range of products including baked/cooked foods. Stevia products have also beneficial uses as herbal and medicinal products and for some more unusual uses, for example, in tobacco products. A fermented extract of stevia showed bactericidal activity against food-borne bacteria including *Escherichia coli* (Tomita *et al.*, 1997). Over 100 phytochemicals have been discovered in stevia. It is rich in terpenes and flavonoids. The constituents responsible for stevia's sweetness were documented in 1931, when eight novel plant chemicals called glycosides were discovered and named. Of these eight glycosides, the one called stevioside is considered the sweetest and has been tested to be approximately 300 times sweeter than sugar (Ishima and Katayama, 1976; Tanaka, 1982). Stevioside, comprising 6–18% of the stevia leaf, is also the most prevalent glycoside in the leaf. Other sweet constituents include steviolbioside, rebaudiosides A-E, and dulcoside A.

In a research, stevia has demonstrated antimicrobial, antibacterial, antiviral, and antiyeast activity. A water extract was shown to help prevent dental cavities by inhibiting the bacteria *Streptococcus mutans* that stimulates plaque formation. Additionally, a US patent was filed in 1993 on an extract from stevia that claimed it to have vasodilatory activity and deemed it effective for various skin diseases (acne, heat rash, and pruritus) and diseases caused by blood circulation insufficiency. Some of the accepted uses, worldwide ethnomedical uses, and nutritional composition are listed in Tables 1–3.

1.4 Traditional Breeding

There is a great variation in phenotype and in leaf analysis among the wild populations of *S. rebaudiana*. The collections made as part of the various breeding and selection research programs have invariably included a range of genotypes and selections of plants with differing levels of steviolosides (Table 4) in their leaves, for example. Shock (1982) planted out 200 lines for survival testing and screened 17 lines for productivity. The stevioside content of leaves can vary substantially (4–16%) between individual plants. This natural

Table 1 Examples of some uses for stevia products and extracts (Midmore and Rank, 2002)

Food and culinary uses	
Soft drinks, cordials, fruit juices	Table top sweetener—for tea, coffee, etc.
Cakes, biscuits	Ice creams, yogurts, sherbets
Jams, sauces, pickles	Pastries, pies, baking
Chewing gum	Jellies, desserts
Seafoods, vegetables	Candies, confectioneries
Diabetic diets	Weight-watcher diets
A source of antioxidants	Flavor, color, and odor enhancers
Alcoholic beverage enhancer (aging agent and catalyst)	
Medicinal uses	
Skin care—eczema and acne control, rapid healing agent	Toothpaste, mouthwashes—plaque retardant/caries preventor
Hypertension treatment and blood pressure control	Diabetic foods and weight loss programs
Bactericidal agent	Pill and capsule additive to improve taste
Calcium antagonist	
Other uses	
Production of plant growth regulators (potential use)	Tobacco additive and flavorant

Table 2 Worldwide ethnomedical uses

Brazil	For cavities/tooth decay, depression, diabetes, fatigue, heart support, hypertension, hyperglycemia, infections, obesity, sweet cravings, tonic, urinary insufficiency, wounds, and as a sweetener
Paraguay	For diabetes, and as a sweetener
South America	For diabetes, hypertension, infections, obesity, and as a sweetener
United States	For candida/thrush (yeast infections), diabetes, hypertension, hyperglycemia, infections, and as a vasodilator and sweetener

variability could be partially due to the largely self-incompatible nature of the flowers. The heritability for yield, leaf/stem ratio, and stevioside content has been studied by Brandle and Rosa

Table 3 Stevia nutrient composition per 100 g (dry weight basis)

Nutrient composition	Per 100 g

Tannins (mg)	0.010

(1992) and Brandle (1999). Studies correlating the plant leaf yield, branch number, and plant height have been reported (Buana and Goenadi, 1985; Shu and Wang, 1988; Buana, 1989). Other studies included correlation between stevioside content and leaf/stem ratio (Tateo *et al.*, 1998), leaf thickness with rebaudioside A (R-A)/stevioside (St) ratio (Shyu *et al.*, 1994). Most breeding programs are based on crossbreeding and selection. Few of the varieties/cultivar selections and releases have been listed in Table 4. Some of these selections, although very high yielding, are self-incompatible and can only be reproduced vegetatively. This limits their commercial use, although they may be useful for breeding new hybrids.

Even with clonal reproduction there can be some variability. An Indonesian study (Nurhaimi and Mathius, 1995) showed variations in DNA fingerprints between six groups of plantlets from an *in vitro* culture indicating some clonal variation. In China, in a sample of plants, one clone varied from the other by 10.26–19.57% in total stevioside content (Huang *et al.*, 1995).

A variety of plant breeding procedures have been used to improve leaf yield and rebaudioside

Table 4 Variety/cultivar selections and releases (Midmore and Rank, 2002)

Year	Location	New variety	Features	References
1979	Korea	Suweon 2	Yield + 22%, steviosides + 12%	Lee <i>et al.</i> , 1978
1982	Korea	Suweon 11	Thick leaves, high rebaudioside A (R-A)%	Le <i>et al.</i> , 1982
1989	China	Yunri, Yunbing		Shu, 1989,
1995	China	Zongping 1	Highest R-A% and St%	Shu, 1995
1994	Taiwan	K1, K2, K3	High yield, better R-A/St ratio	Shyu <i>et al.</i> , 1994
1994	Indonesia	BPP 72		Suhendi, 1989

1996	Russia	Ramonskaya Slastena		Kornienko and Parfenov, 1996

A content in the leaves. Based on cultivar descriptions from Japan, China, and Korea, it appears that sufficient genetic variability exists to make significant genetic gains in leaf yield, rebaudioside A content, and the ratio of rebaudioside A to stevioside (Morita, 1987; Brandle and Rosa, 1992; Shyu *et al.*, 1994; Shizhen, 1995).

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Stevia is generally self-incompatible. Therefore, it is difficult to increase the commercial production (Monteiro, 1980; Toffler and Orio, 1981) by means of the conventional sexual seed production. In general, propagation of stevia is largely employed by the means of seeds but it is not an adequate procedure because it results in populations with a wide random variation (Tamura *et al.*, 1984; Nakamura and Tamura, 1985) in several important characters, such as glycoside content. Variation in glycoside content has been reported to vary between 5% and 20%. Germination and establishment from seed are often poor and sometimes unsuccessful. Stevia is a cross-pollinated species requiring the presence of pollen from other plant to produce a viable seed, which often is an obstacle in the absence of appropriate means of pollen transfers. On the other hand, limited vegetative propagation (Sakaguchi and Kan, 1982) is also a major constraint in stevia production.

Stevia is likely to become a major source of high-potency sweeteners for the growing natural food market in the future, but the crop yields are compromised by such inherent failures that pose a problem where conventional breeding is desirable to design alternative methods for the

rapid production of plants with high and uniform yields of sweeteners. On this account, cloning of selected plants seems to be the desirable approach for obtaining homogeneous populations. Available data on tissue culture of this species indicate that *in vitro* propagation may be a useful alternative for this purpose. Moreover, exploration of *in vitro* generated variability and *in vitro* selection methods may also be advantageous as a source of new stevia genotypes. Clonal propagation is practical for small-scale production, but is probably not economically viable for large-scale stevia production where labor costs are high.

To overcome these constraints, it is important to develop alternative methods for rapid production of transgenic homogenous population with a high and uniform yield of sweetener plants.

2. DEVELOPMENT OF TRANSGENIC STEVIA

At present, several innovative methods are available to insert genes into plant genome and generate transgenic plants. The types of approaches chiefly used are mechanical, electrical, and chemical (Table 5). These approaches involve the specific techniques such as microinjection, particle bombardment or biolistic gun (Christou, 1996), electroporation (Potrykus, 1995), and *Agrobacterium*-mediated transformation (Hooymaas, 1995). These techniques are widely used and are versatile and safe, but are substantially less efficient than viruses. The major challenge of DNA delivery is to develop a system that is both highly efficient in delivery/expression and applicable to basic research as well as clinical settings. Albeit the availability of all these techniques, least work has

Table 5 Summary of DNA transfection methods

Approach	Method

	Dendrimers
	Other polymers (including controlled-release polymers)

been done on stevia. Dhir *et al.* (2005) have taken an initiative in the transgenic research of stevia.

2.1 Electroporation-Mediated Gene Transfer in Stevia Protoplasts

Electroporation is a technique widely used for gene transfer in animal, plant, or microbial systems. It has the advantages of being simple, effective, and applicable to a wide range of plant species, and can be used to deliver DNA into large numbers of cells within a very short time (Wu and Feng, 1999). Until recently, success with electroporation has been limited to protoplasts (Potrykus, 1995); however, it is now feasible to deliver DNA via electroporation directly into certain intact plant cells.

Electroporation is the use of short high-voltage pulses to overcome the barrier of the cell membrane. By applying an external electric field, which just surpasses the capacitance of the cell membrane, transient and reversible breakdown of the membrane can be induced. This transient, permeabilized state can be used to transfer a variety of different molecules into the cells, either through simple diffusion in the case of small molecules or through electroporetically driven processes allowing passage through the destabilized membrane as is the case for DNA transfer. Electroporation was initially started for gene transfer but now is in use for delivery of a large variety of molecules starting from ions to drugs, dyes, tracers, antibodies, and oligonucleotides to RNA and DNA. Electroporation-mediated gene transfer has been achieved in stevia protoplasts (Figure 1). The typical procedure for the gene transfer can be subdivided as follows.

2.1.1 Protoplast isolation and purification

In vitro raised plants were used for protoplast isolation. Different explants (leaves, petioles, roots, stems, and hypocotyl) from 3-week-old plants were collected and thinly sliced with a surgical knife. Approximately 1 g (fresh weight) of each explant was incubated in 10 ml of filter-sterilized (Millipore, 0.22 μ m pore size) enzyme solution consisting of different concentration of cellulase “Onozuka” R-10, macerozyme, driselase, and pectolyase Y-23, and 9% mannitol in cell protoplast wash (CPW) salt mixture (MgCl_2 , CaCl_2 , and KNO_3). The pH of the enzyme solution was adjusted to 5.8. Cell wall digestion of explants was carried out in a disposable multivessel dish overnight in dark at $26 \pm 2^\circ\text{C}$ with gentle swirling (50–60 rpm) on a gyratory shaker.

After cell wall digestion, the protoplasts were carefully observed with an inverted microscope. The crude protoplast suspension was filtered through mesh and centrifuged. The pelleted protoplasts were resuspended and washed once with Kao and Michayluk (KP8; 1975) culture medium to remove the enzyme solution and centrifuged for another 10 min.

2.1.2 Electroporation and protoplast culture

Viable protoplasts obtained from the previous step will then be transferred into the electroporation cuvettes, previously filled with 1 ml of electroporation buffer containing 0–25 μ g of DNA per milliliter. To optimize the electric pulse parameters, different voltages (50–400 V) were tested by the 960 μ F capacitor (Bio-Rad Gene Pulse, Hercules, CA, USA). After the electric pulse was delivered, cuvettes containing the protoplasts were incubated for 10 min on ice, and were subsequently cultured for 48 h at $24 \pm 2^\circ\text{C}$ before being harvested for gene expression assay. Electroporated and nonelectroporated protoplasts were diluted and cultured with KP8 media to a concentration of 1 million protoplasts per milliliter (5 ml per dish). The petridishes were wrapped with parafilm to maintain humidity and prevent contamination. The sealed dishes were kept in dark at $26 \pm 2^\circ\text{C}$ in a culture box. Control protoplasts were either untreated, incubated in

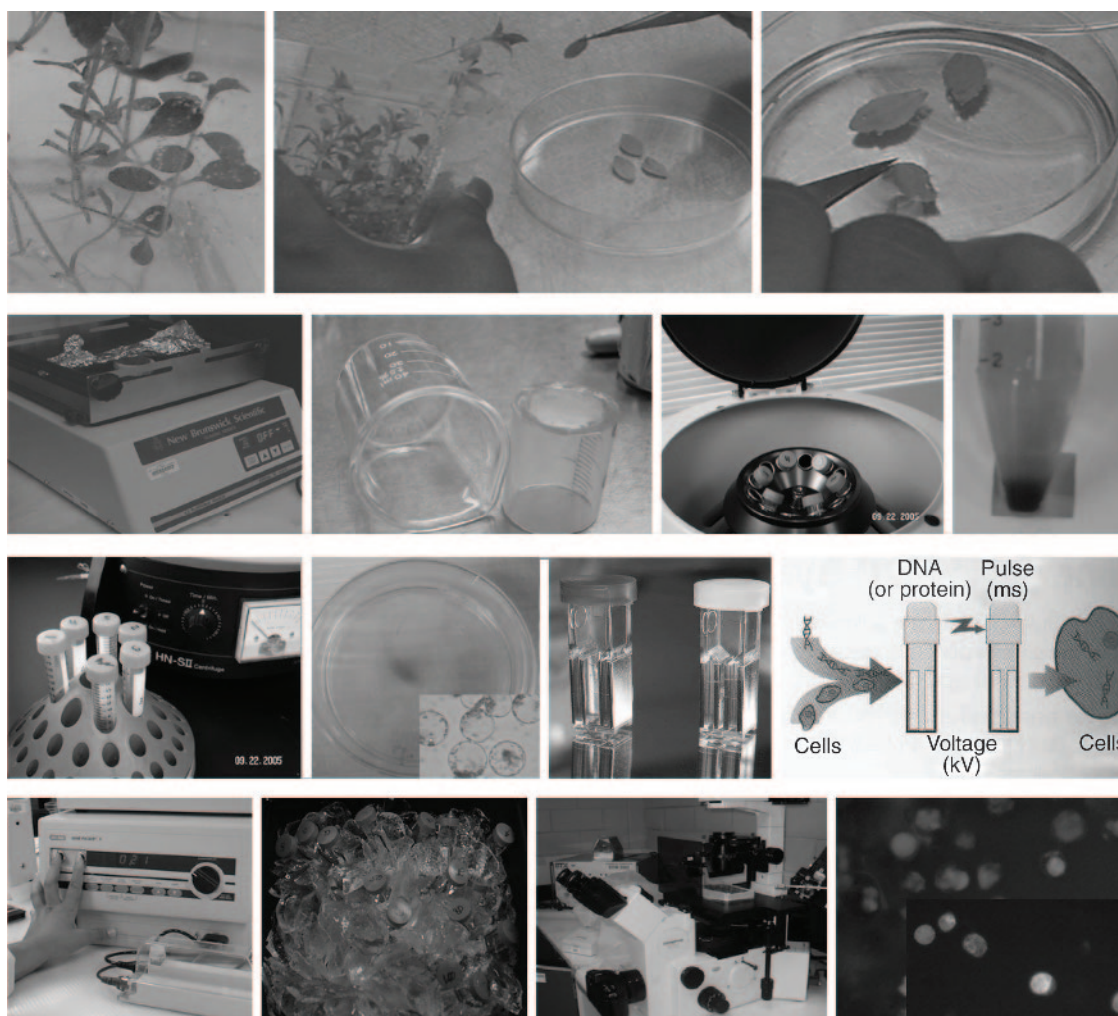

Figure 1 Stevia protoplast isolation, purification, and culture for genetic transformation through tissue electroporation

buffer and plasmid DNA but not electroporated, or electroporated with an equal volume of buffer to replace the DNA solution.

Five different buffers were used to study their effect on gene expression: (1) HEPES (4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid)-buffered mannitol (HBM)—0.55 M mannitol, 1 mM HEPES pH 7.0 (Nagata, 1989); (2) HEPES-buffered saline (HBS)—5 mM KCl, 137 mM NaCl, 0.7 mM Na_2HPO_4 , 600 mM glucose, 21 mM HEPES pH 7.2 (Dhir *et al.*, 1991); (3) EPR (electroporation)—9.0% glucose, CaCl_2 , 4 mM N-2 hydroxyethyl-piperazine-N2-ethanesulfonic acid (HEPES) and 0.2 spermidine; (4) KP8—medium,

9 M CPW (9% mannitol, MgCl_2 148 mg/l and KNO_3 101 mg/l; (5) 13 M mannitol 150 mM NaCl, and 5 mM CaCl_2 . Samples were preincubated in each buffer for 1 h and later prepared for electroporation as described above.

2.1.3 Factors affecting electroporation

2.1.3.1 Effect of different explants on protoplast viability

Direct observations under the inverted microscope have revealed that maximum digestion of cell walls

Table 6 Effect of enzyme combinations on protoplast yield and viability

Cellulase Onozaka-10 (%)	Macerozyme Onozaka-R (%)	Driselase (%)	Pectolyase Y-23 (%)	Yield of protoplast (gram fresh weight)	Viability of protoplasts (%)
1.5	1.0	0.2	0.1	7×10^6	75–85
1.5	1.0	0.5	0.1	5×10^6	85–90
2.0	1.5	0.2	0.1	5×10^5	85–90
2.0	1.5	0.5	0.1	5×10^5	95

occurred in the leaf tissue (approximately 90% converted protoplasts were viable). In comparison to the leaf explants, the conversion of cells into protoplasts for the petiole was 80%, hypocotyls 50%, stem 70%, and root 30%. The protoplasts, which were measured using the micrometer, varied in size from 20 to 40 μm . A range of enzyme combinations have been tested to digest the tissue and isolate the protoplast (Table 6); leaf explants were found to yield higher amount of protoplasts. The released protoplasts settled to the bottom of the multivessel dish and can be used for downstream processes (Figure 1).

2.1.3.2 Plasmid DNA

The transient expression assay vector pCambia 1304 (CAMBIA GPO Box 3200, Canberra ACT 2601, Australia) carries a selective marker gene (*hptII* (hygromycin phosphotransferase)) conferring hygromycin resistance and a fusion

between the reporter genes coding for β -glucuronidase (GUS) (*uidA*) and a green fluorescent protein (GFP) (*mgfp5*), both driven by a 35S promoter from cauliflower mosaic virus (CaMV) (Figure 2). Plasmid DNA was independently transformed into *E. coli* JM109 (Dower *et al.*, 1988) or DH5a (Hanahan, 1983) cells and purified by the cesium chloride method (Sambrook *et al.*, 1989). Supercoiled plasmid DNA was directly employed in transformation experiments or linearized by digestion with *EcoRI* (GIBCO BRL). Concentrations of plasmid DNA were spectrophotometrically determined at 260 nm and confirmed by tris-borate-ethylene diamine tetraacetic acid gel electrophoresis in 0.8% agarose gels (Sambrook *et al.*, 1989).

2.1.3.3 Effect of DNA concentration

With varying plasmid DNA concentration from 0 to 25 $\mu\text{g ml}^{-1}$, the number of green protoplasts

Figure 2 The map of transient expression assay vector pCambia 1304 (<http://www.cambia.org/daisy/cambia/2049/version/1/part/4/data/pCAMBIA1304.pdf?branch=main&language=default>)

Figure 3 Influence of plasmid DNA concentration on the number of transformed (*GUS* gene expressing) protoplast cells of stevia; the electroporation was performed at 200 V

increased (Figure 3). With increasing the plasmid DNA concentration ($50\text{--}100\ \mu\text{g ml}^{-1}$), the number of blue protoplasts declined. Plasmid DNA of 15 to $20\ \mu\text{g ml}^{-1}$ was found to be optimal for efficient expression. An increase in the DNA concentration would infer directly to an increase in gene expression. However, if the DNA concentration is too high, uptake might possibly be decreased due to competition with DNA strands for protoplast uptake (Dhir *et al.*, 1991).

2.1.3.4 Effect of field strength on protoplast viability

Transient expression of a gene coding for a GFP (Chalfie *et al.*, 1994) can be used for *in vivo* evaluation of transformation efficiency. To maximize the expression of introduced DNA into protoplast, it is important to test protoplast viability under different ranges of electric field. The viability of protoplasts prior to electroporation was approximately higher (95%). Two hours after a single

pulse electroporation, at voltages ranging from 50 to 400 V, the viability decreased from 95% to 27%. In order to test the number of pulse on protoplast viability, protoplasts were pulsed twice at voltage ranging from 50 to 400 V. Viability decreased from 75% to 6% with increasing voltage. However, at 100–200 V single pulse, the viability was 80–63% which is considered to be optimal for DNA delivery after electroporation (Dhir *et al.*, 1992). Such a combination induces more pores, larger pores, or longer lived pores in the plasma membrane, allowing more DNA uptake (He and Lazzeri, 1998).

2.1.3.5 Effect of field strength on transient gene expression

A known amplitude of 100 V field strength is reported to be an optimal value for electroporation of rice leaf base tissue (Dekeyser *et al.*, 1990). However, at this amplitude, the number of green fluorescent protoplasts was approximately 2500. By increasing the voltage from 100 to 250 V,

the number of green fluorescent protoplasts also increased but beyond 250 V the number of protoplasts expressing the *GFP* gene decreased due to decline in tissue viability. Maximum transient gene expression has been reported under electric field strengths causing more than 50% reduction in protoplast viability (Fromm *et al.*, 1985; Hauptmann *et al.*, 1987; Oard *et al.*, 1989). This indicates that the expression of *GFP* gene increased in proportion to the voltage, suggesting a correlation with number and/or size of pores in electroporated cells (Nagata, 1989). Almost complete death of tissues has been reported at 400 V.

2.1.3.6 Effect of different electroporation buffers

Different types of electroporation buffers with varying amounts of high or low ionic strength had significant effect on DNA uptake. EPR at pH 7.2 showed maximum green protoplasts, approximately 3300 per electroporated sample. Larkin *et al.* (1990) reported that the expression of DNA in tobacco protoplasts was positively correlated with pH up to 9.0, possibility due to charge modification and destabilization of the plasma membrane at high pH. Nonviable and damaged protoplasts were rarely seen after electroporation in buffer EPR, which gave almost 100% expression of *GFP*. However, the frequency of stable transformation was lower than that expected from transient gene expression in electroporated protoplasts (Hain *et al.*, 1985; Shillito *et al.*, 1985), probably due to some retention of transgene expression ability in damaged protoplasts for periods shorter than 72 h. The chloride ions in buffer HBS and HBM resulted in the production of toxic chlorine gas when electric pulses were applied, leading to a reduction in cellular viability.

2.1.4 Analysis of GFP expression

Electroporated protoplasts will finally be resuspended in culture medium (Kao (1977) modified by Gilmour *et al.* (1989)) to give 1.0×10^6 protoplasts per milliliter per liter and kept in the dark for 24 h at 4 °C. Nonelectroporated protoplasts in 800 ml of electroporation buffer with 10 mg of

plasmid DNA were ice incubated for 45 min. As a measure of transformation efficiency, the number of transgene-expressing and nonexpressing protoplasts will be scored using fluorescence microscopy at 395 nm (Figures 1 and 4). The viability of the tissue after electroporation can be measured with phenosafranine and by visual observation of cell damage (Dhir *et al.*, 1991). Putative transgenic plants of stevia can be obtained at high frequencies from electroporated protoplasts while an effective plant regeneration protocol is used.

2.2 Genetic Transformation and Plant Regeneration in Stevia Using Microprojectile Bombardment

Microprojectile or particle bombardment, also called biolistic particle delivery, can introduce DNA into many cells (including cell-walled plant cells) simultaneously. In this procedure, DNA-coated microparticles (composed of metals such as gold or tungsten) are accelerated to high velocity to penetrate cell membranes or cell walls (Yang *et al.*, 1990; Ye *et al.*, 1990; Yang and Sun, 1995). Because of the difficulty in controlling the DNA entry pathway, this procedure is applied mainly in adherent cell cultures and has yet to be widely used systemically. Stevia is generally self-incompatible, therefore it is difficult to increase the commercial scale production through conventional sexual means. Limited or no work has been done on stevia transformation through particle bombardment. Dhir *et al.* (unpublished) has successfully performed certain pilot experiments for genetic modification of stevia using such improvised technique. Rigorous testing is inevitable to establish a successful transient and stable transformation protocol. Numerous parameters affect the efficiency and success of gene transfer through particle bombardment; those include mainly distance between stopping plate and target tissue, helium pressure, number of bombardment, and type of particles (tungsten or gold). The results from various preliminary research projects showed that for stevia leaf-derived callus the optimum parameters would be 6 cm distance, 1100 psi He pressure, gold particles, and one bombardment. The expression of GFP in tissue can be observed after 12 h of bombardment

Figure 4 Electroporation-mediated stable genetic transformation of *Stevia rebaudiana* protoplasts: (a) freshly isolated mesophyll protoplast; (b) first cell division; (c) protoplast-derived cell colony; (d) clusters from protoplast-derived cells; (e) microcalli in agarose in bead; (f) somatic embryos formed on MS medium; (g) *GFP* gene expression in stevia mesophyll protoplast red fluorescence is nontransformed cell; (h) expression of *GFP* gene in protoplast; (i) *GFP* expressing protoplast in four-cell division stage; (j, k) *GFP* gene expressing microcolonies after 3–4 weeks of culture; and (l) nontransformed and transformed stevia leaf

and GFP expression has been found stable in the embryogenic callus.

2.3 Culture, Micropropagation, and Plant Regeneration in *Stevia* as Prerequisites for Development of Transgenics

2.3.1 Explants used and their preparation

Explants for culture can be obtained either from seeds or a mature plant itself. The seeds of stevia were surface sterilized (12 min in 15% bleach and washed three times with sterile distilled water) and germinated *in vitro* in Murashige and Skoog (MS) medium (Murashige and Skoog, 1962) without growth regulators but containing 30 g l^{-1} (w/v) sucrose and solidified with 3 g l^{-1} (w/v) Gelrite (Phytotechnology) at $24 \pm 2^\circ \text{C}$ with a 16/8 h

light/dark photoperiod. Explants can also be obtained from plants already growing *in vivo*. These plants can be either in greenhouse, field, or in wild, but standard aseptic techniques should be followed. Typical explants used for tissue culture experiments are shoot tips (1–3 cm long with axillary bud), leaves, stems, and roots. On regular basis, the explants are generally surface sterilized with 70% ethanol for 10 s, followed by immersion in 15% Clorox solution for 15 min, and then rinsed with sterile water three to four times. The culture media typically contains 3% (w/v) sucrose or maltose and 0.3% (w/v) Phytogel. The pH of all media is adjusted to 5.8 prior to autoclaving at 121°C for 20 min at 15 psi. The cultures are maintained at $26 \pm 2^\circ \text{C}$ and a light/dark cycle of 16/8 h under a photon irradiance of $120 \mu \text{M m}^{-2} \text{s}^{-1}$. The explants are subcultured routinely onto fresh medium every

2–3 weeks. *In vitro* raised plants (Figure 4) can then be used for protoplast isolation and transformation experiments.

2.3.2 Micropropagation

The seeds of stevia show a very low germination percentage (Felippe *et al.*, 1971; Felipe and Lucas, 1971; Monteiro, 1980; Toffler and Orio, 1981). Propagation by seeds does not allow the production of homogeneous populations and results in high variability in important features like sweetening levels and composition (Tamura *et al.*, 1984; Nakamura and Tamura, 1985). Vegetative propagation is also limited by the lower number of individuals that can be obtained simultaneously from a single plant (Sakaguchi and Kan, 1982). Among various other parts, stevia's nodes are quite often used for micropropagation. It has been observed that cutting the shoot 0.5–1 cm above the node and 4–6 cm below the node is an appropriate size to use for propagation. Once the desired size of the cuttings is made, they can then be placed on MS media for normal regeneration and growth (Figure 5). In 2–3 weeks' time, the plants are regenerated. By this time the multiple axillary meristems were already developing in the shoot tip. The production of shoots is even greater during the second subculture, as observed in *Acacia nilotica* (Dewan, 1992). This fact can be explained as a result of the release of apical dominance imposed by the apical shoot. If the shoot tip or apical shoot had been excised at the time of first subculture, the frequency of shoot might eventually be greater. The rooting can be initiated in shoots longer than 1–2 cm using MS medium supplemented with 5.71–22.84 μM indole-3-acetic acid (IAA) or indole-3-butyric acid (IBA). Plantlets with roots were transferred to basal medium for 1 month and then to small pots filled with garden soil and sand (1:1). Standard statistical procedures should be followed in experimental design. Plant material was subcultured onto fresh medium at 4 weeks intervals.

2.3.3 Somatic embryo induction

Somatic embryogenesis has been described for more than a hundred plant species (Terzi and Loschiavo, 1990), but the number of reports of

somatic embryogenesis among members of the Asteraceae family is still low (May and Trigiano, 1991). The development of protocols for regeneration of stevia via somatic embryogenesis is important as this technique can be used in the clonal propagation of this plant, or as explant material for protoplast isolation and regeneration (Puite, 1992). For embryogenic culture induction, leaf segments (1–2 cm long) are removed from 5 to 6-week-old *in vitro* raised plants. Leaf segment will then be incubated (adaxial side down) on MS medium supplemented with B5 vitamins, 30 g sucrose and 3 g Gelrite. 2,4-dichlorophenoxyacetic acid (2,4-D) is used in combination with each of three cytokinins: 6-benzyl adenine (BA), kinetin (KN), and zeatin. The auxin 2,4-D used with the range of 1.35 and 4.52 μM in combination with BA (1.33–4.43 μM), KN (0.86, 2.28 μM) allowed a high percentage of culture induction in leaf segments (65–93% 2,4-D/BA; 53–85% 2,4-D/KN; and 49–65% 2,4-D) within 6 weeks (Dhir *et al.*, unpublished). The proembryogenic masses will appear after 8 weeks of subculture. Within 2–3 weeks of subcultures, somatic embryos will appear on the surface of cultures.

2.3.4 Embryo maturation

After 9 weeks (three subcultures), callus tissues (initiated from leaf explants) with somatic embryos at the globular state that were including different media were transferred onto embryo induction medium. Dhir *et al.* (unpublished) tested three auxins: 2,4-D (3.16 μM), α -naphthaleneacetic acid (NAA) (3.75 μM), and IBA (3.44 μM) in combination with one each of two cytokinins, BA (0.44 or 1.33 μM), KN (46 or 1.39 μM). Cultures on induction medium (at globular and heart-shaped embryos) supplemented with BA and 2,4-D were transferred for somatic embryo maturation and germination onto media supplemented with BA in combination with 2,4-D, NAA, or IBA. The temperature, photoperiod, and light intensity were same as described above. Numbers of callus-forming explants, calli-producing embryos, and mature/germinating embryos were recorded at the end of each subculture phase. Somatic embryo formation and development were performed after transferring cultures on embryo maturation and germination medium, MS medium supplemented

Figure 5 Micropropagation and plant regeneration of *Stevia rebaudiana*

with $3.44 \mu\text{M}$ IBA and $0.44 \mu\text{M}$ BA. Different stages of somatic embryo development (globular stage, heart- and torpedo-shaped somatic embryos, cotyledonary stage, germinating embryos, and embryo-desired plantlet) are shown on maturation and germination media (Figure 6).

2.3.5 Plant regeneration

Mature somatic embryos that had undergone germination to form plantlets were excised from calli. After the plantlets reached 3–4 weeks, they were transferred to pots with vermiculite and grown for 6–8 weeks in growth chambers for

acclimatization, after which they were transferred to bigger pots and greenhouse. Experiments were repeated three to five times. Plantlets transferred to Magenta boxes (four per boxes) containing rooting medium that contained double strength MS medium, with gibberellic acid A3 (GA3) $2.89 \mu\text{M}$ and NAA $5.37 \mu\text{M}$ (Figure 6).

3. FUTURE ROAD MAP

The great interest in stevia as a noncaloric, natural sweetener has fueled many studies on it, including toxicological ones. The main sweet chemical, stevioside, has been found to be nontoxic

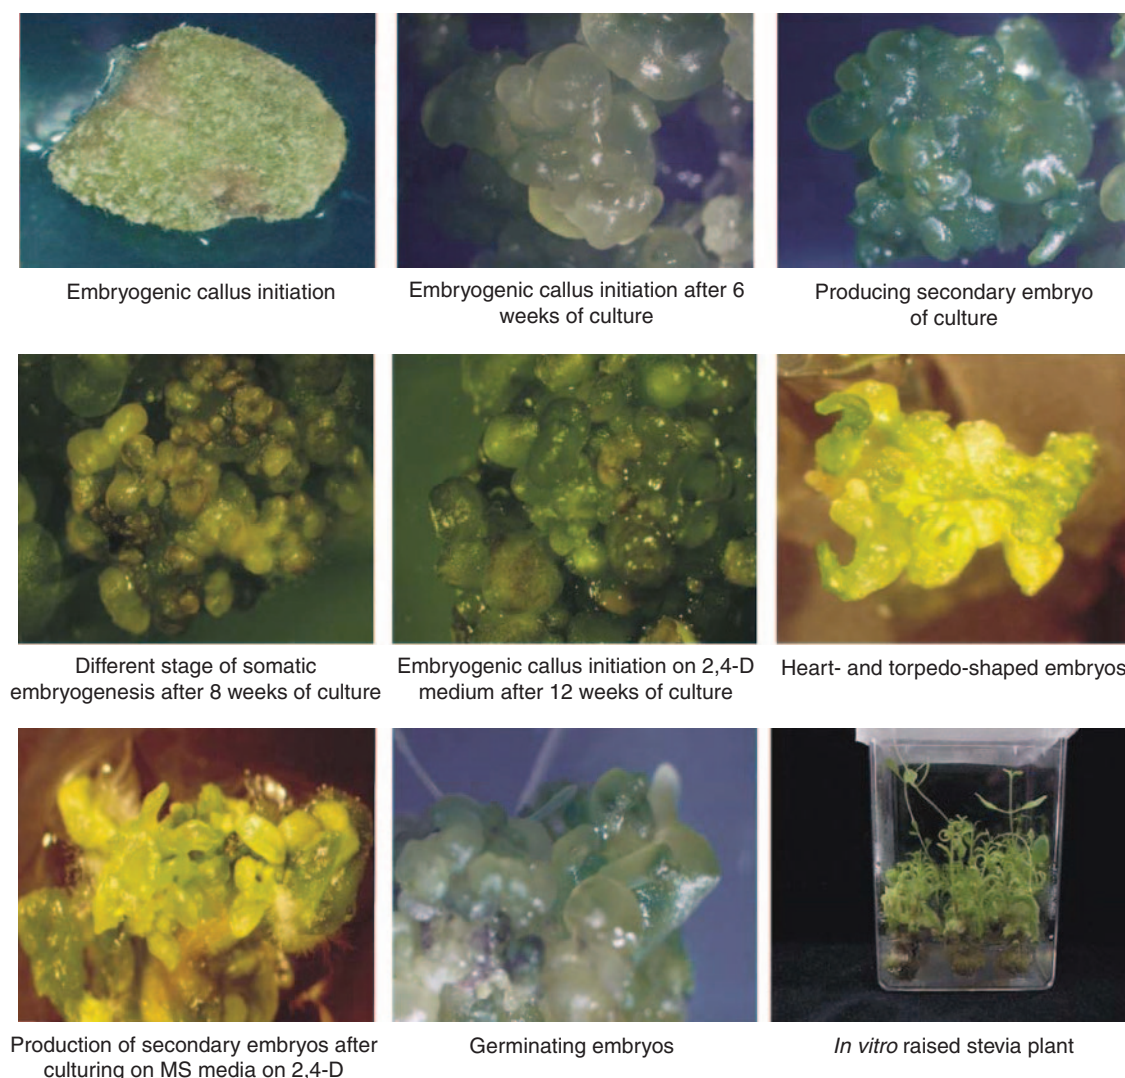

Figure 6 Callus induction, somatic embryogenesis, and plantlet regeneration of *Stevia rebaudiana*

in acute toxicity studies with rats, rabbits, guinea pigs, and birds. It also has been shown not to cause cellular changes (mutagenic) or to have any effect on fertility. However, studies conflict as to the effect of stevia leaf on fertility. The majority of clinical studies show stevia leaf to have no effect on fertility in both males and females. In one study, however, a water extract of the leaf was shown to reduce testosterone levels and sperm count in male rats.

In 1991, at the request of an anonymous complaint, the US Food and Drug Administration (FDA) labeled stevia as an “unsafe food additive” and restricted its import. The FDA’s stated reason was “toxicological information on stevia is

inadequate to demonstrate its safety.” This ruling was controversial, as stevia proponents pointed out that this designation violates the FDA’s own guidelines, under which any natural substance used prior to 1958 with no reported adverse effects should be recognized as safe.

Contraindications:

- Stevia leaf (at dosages higher than used for sweetening purposes) has been documented to have a hypoglycemic effect. Those with diabetes should use high amounts of stevia with caution and monitor their blood sugar levels as medications may need adjusting.

- Stevia leaf has been documented to have a hypotensive, or blood pressure lowering effect (at dosages higher than used for sweetening purposes). Persons with low blood pressure and those taking antihypertensive drugs should avoid using large amounts of stevia and monitor their blood pressure levels accordingly for these possible effects.

Drug Interactions. In large amounts, it may potentiate antihypertensive and antidiabetic medications.

Today, stevia leaves and leaf extracts are commonly found in most health food stores; however, they may only be sold in the United States as dietary/herbal supplements, not as food additives or sweeteners. In fact, in 1991 the FDA even banned all imports of stevia into the country. This political move was viewed by many to have monetary ties to the sweetener industry, which stood to lose a lot, and it created a huge public outcry in the natural products industry. The import ban was lifted in 1995 after much lobbying led by the American Herbal Products Association and other industry leaders. This allowed stevia to be sold as a dietary supplement under new legislation called the Dietary Supplement Health and Education Act of 1994.

A lot of efforts have been put forth by researchers in the last one decade for better understanding the stevia. The first linkage map of stevia has been constructed, which will lay a foundation for molecular breeding efforts (Yao *et al.*, 1999). Expressed sequence tags are providing a new approach to gene discovery in stevia's secondary metabolism. Transcripts involved in diterpene synthesis have been investigated to understand the steviol glycoside biosynthesis (Brandle *et al.*, 2002). Functional genomics has been successfully utilized in uncovering the three major glucosyltransferase involved in the synthesis of the major sweet glucosides of stevia (Richman *et al.*, 2005).

There is need for creating awareness among the people about stevia's availability and its potential as a low-calorie sweetener, which is of significant nutritional and therapeutic values. Growing demand for herbal foods might encourage stevia cultivation and production and would help enjoy the sweet taste with minimal calories for those who are on restricted diet for sugar/carbohydrate.

1. INTRODUCTION

1.1 History, Origin, and Distribution

Potato (*Solanum tuberosum* L. subsp. *tuberosum*) is a crop of New World origin, but exactly when and where potato was first cultivated are subjects of debate. Evidence comes from archeological artifacts and plant remains, written accounts of early New World explorers, and molecular data.

Salaman (1937), Laufer (1938), Hawkes (1967, 1990), and Sauer (1993) reviewed archeological evidence for ancient consumption and possible cultivation of potato, including carbon dated plant remains and ceramics depicting potatoes. Ugent *et al.* (1987) reported preserved tuber skins collected from fire pits at a site inhabited 13 000 years ago at Monte Verde in southern Chile. Based on phase contrast and scanning electron microscopy analysis of starch grains, the authors identify the remains as *Solanum maglia*. However, Hawkes (1990) argues that the remains cannot be *S. maglia*, extant populations of which do not occur in the region. Grun (1990) raises similar concerns. Whatever the species identity of the remains, however, Hawkes (1990) agreed with Ugent *et al.* (1987) that the archeological context in which they were discovered points to human consumption of potato tubers predating the establishment of agriculture. Engel (1970)

reported fossilized potato tubers recovered from a central Peruvian cave inhabited 10 000 years ago. While Engel (1970) only identified the tubers as *Solanum* sp., Ugent *et al.* (1982) later concluded they may be *S. tuberosum* based on phase-contrast microscopy of starch grains. It remains unclear whether the tubers were cultivated or gathered from the wild. Similarly, Martins (1976) identified tuber remains from the Puna de Chilca Canyon of the Peruvian highlands as *S. tuberosum* based on light and scanning electron microscopy of gross morphology, starch grains, cork cells, and distribution and organization of xylem vessels. The samples are approximately 8000 years old. Archeological evidence of early human consumption of *S. tuberosum* was also reported by Ugent *et al.* (1982). A total of 20 tubers, recovered from four sites near Casma in the subtropical coastal desert of central Peru, were identified as *S. tuberosum* on the basis of surface features and phase contrast microscopy of starch grains. Carbon dating revealed these tubers to be 3200–4000 years old. While the arid conditions near Casma favored the preservation of the potato tubers, the climate is inhospitable to *Solanum* species. Pozorski and Pozorski (1979) reported evidence that the ancient inhabitants of coastal regions of Peru practiced irrigation agriculture. Thus, Ugent *et al.* (1982) argue that potato remains found at Casma may have

originated from intentional cultivation rather than foraging. But Sauer (1993) argues that the relative paucity of potato remains at Peruvian coastal archeological sites suggests that potatoes may have been harvested from the highlands and transported to the coast, rather than cultivated by coastal inhabitants themselves.

Clay phytomorphic representations of potato support archeological evidence that potato was a food crop known to the ancient people of South America. Potato ceramics first appeared about 2000 years ago in northern (Moche and Chimú) and southern (Nazca) coastal Peruvian cultures (Sauer, 1993). In some instances, clay pots depicted highly stylized potatoes, often adopting humanlike characteristics (Hawkes, 1967, 1990). Some potato pots depicted *chuño*, a freeze-dried potato product produced even today in the Andean highlands (Sauer, 1993). Presumably, *chuño* would have been known to the ancient coastal Peruvian potters through trade with highland people since it could not have been produced at lower altitudes. Hawkes (1990) further describes ceramic potato pots from coastal regions as “rare” and argues that, owing to poor potato production conditions along the coast, potters would have been familiar with all types of potato mainly through trade with highland people.

Archeological evidence clearly indicates that potato was first cultivated in South America. Consistently, Vavilov (1951) identified as the center of origin for potato a broadly defined New World region encompassing Mexico, Peru, and adjoining countries. Even before that time, scientists had debated both exactly where potatoes were first domesticated, with the Andean highlands of Peru and Chile/Argentina/Bolivia being leading contenders, and whether potato was domesticated once or multiple times. Spooner *et al.* (2005) examined relationships among 261 wild potato and 98 cultivated potato landrace accessions. Based on 438 amplified fragment length polymorphism (AFLP) markers, the wild accessions could be divided into “Northern” (Peru) and “Southern” (Bolivia and Argentina) clades. Relationships within these clades were poorly resolved and the authors conclude that further systematic study and possible taxonomic revisions are warranted. Significantly, the data also support a single domestication event for all cultivated potatoes. Cultivated potato is most closely related

to northern wild accessions, suggesting that modern-day cultivated potato originated from wild accessions in what is present-day southern Peru (Spooner *et al.*, 2005). The conclusions of Spooner *et al.* (2005) based on robust molecular analysis differ from those of earlier authors who argue for multiple domestication events possibly involving complex and cryptic interspecific hybridization (Ugent, 1970; Grun, 1990; Hosaka, 1995; van den Berg *et al.*, 1998; Huaman and Spooner, 2002) and a greater involvement of southern accessions (Bukasov, 1978; Hawkes, 1990; Ochoa, 1990) in the origin of cultivated materials.

Exploration of the New World by early European explorers led ultimately to the introduction of potato to the Old World. Salaman (1937), Laufer (1938), and Hawkes (1967, 1990) offer detailed analyses of this subject. The introduction of potato into Europe is steeped in folklore. By some accounts, potatoes were first transported from South America by Sir Francis Drake as a result of his famed circumnavigation of the globe (1577–1580). However, several authors have pointed out that potato tubers surely would not have survived the 2-year westward voyage from South America back to Europe (Hawkes, 1990; Sauer, 1993). Another legend attributes introduction of the potato into Ireland to Sir Walter Raleigh in the late 1580s, an assertion supported by Salaman (1937) but refuted by McNeill (1949). Alternatively, Salaman (1937) and Laufer (1938) estimate that potato may have first been introduced from South America into Spain around 1570 since it was not mentioned in a published account of the flora of the region by botanist Clusius (Charles de l’Ecluse), who visited Spain in 1564. Hawkes (1990) concurs with this estimate. From Spain potato traveled to Italy where it became a food crop of regional significance. Later, it spread throughout Europe and Clusius first reports seeing potato tubers in 1588 in Belgium, these having arrived from Italy in 1587 (detailed in Laufer, 1938). Around 1590, potato arrived in England, perhaps through direct shipment from the New World (Hawkes, 1990). Potato is described in the 1596 garden catalog of English botanist John Gerard (Salaman, 1937; Laufer, 1938; Glendinning, 1983). In the centuries that followed, potato became a staple crop throughout much of Europe, supporting the rapid population

expansion that accompanied the Industrial Revolution (Grun, 1990).

From Europe, the potato was transported to North America. Potatoes may first have been transported from England to Bermuda in 1613 and then from Bermuda to the North American mainland in 1621, a hypothesis favored by Laufer (1938) and Hawkes (1990). Potato was present in India by 1610 and mainland China by 1700 (Sauer, 1993). Potatoes were taken to New Zealand in 1769 by Captain Cook and gained agronomic significance for the native Maori by 1840 (Sauer, 1993). Missionaries may have played a crucial role in distribution of the potato from Europe throughout the world (Laufer, 1938; Sauer, 1993).

1.2 Taxonomy, Habit, Habitat, Genome Size, and Cytological Features

The Solanaceae, also known as the potato family or the nightshade family, is a large plant family distributed throughout the Old and New Worlds. The family encompasses many important agronomic and horticultural crops, with the genus *Solanum*, from which the Solanaceae gets its name, being the most economically significant genus. Depending on whose taxonomy one follows, *Solanum* includes 1000 (D'Arcy, 1991) to 1700 (Mabberley, 1997) species, making it one of the largest of all plant genera. *Solanum* includes three significant food crops, potato (*S. tuberosum*), tomato (*S. lycopersicum*), and eggplant (*S. melongena*). Other species in the genus include food crops of minor or regional significance, e.g., pepino (*S. muricatum*), scarlet eggplant (*S. aethiopicum*), and gboma eggplant (*S. macrocarpon*) and weed species, e.g., nightshade (*S. nigrum*) and *S. sisymbriifolium*. On a worldwide scale, potato is the most important food crop in the genus, with nearly 325 million metric tons produced in 2005, ranking potato as the world's fourth most important human food crop behind maize (702 million metric tons), wheat (630 million metric tons), and rice (618 million metric tons) (FAOSTAT data 2005).

Based on morphological and molecular data, *Solanum* may be divided into several subgenera. Subgenus *Potatoe* includes approximately 200 tuber-bearing and nontuber-bearing potato species. These species are exclusively of New World

origin and are found naturally distributed throughout the southwestern United States, Mexico and Central America, and South America. The slopes of the Andes Mountains are particularly rich in potato species. Crossability between these related potato species is mediated through the Endosperm Balance Number (EBN). According to the EBN hypothesis of Johnston *et al.* (1980), genetic factors within the potato genome determine the inherent EBN for the species. EBN values for potato species include EBN 1, 2, and 4. For an interspecific cross to be successful, the endosperm of the developing seed must carry a maternal:paternal EBN ratio of 2:1. EBN can be manipulated by altering parental ploidies through use of $2n$ gametes or artificial procedures (Carputo and Barone, 2005). Mismatched EBNs have limited gene flow between certain potato species, especially between the evolutionarily primitive 1EBN species and cultivated potato (4EBN). Hawkes (1990) provides the most recent complete taxonomic treatment of the potatoes, although subsequent research (e.g., Rodriguez and Spooner, 1997; Spooner and Castillo, 1997; Lara-Cabrera and Spooner, 2004; Spooner *et al.*, 2004) points to a clear need for further systematic study and taxonomic refinement. More recent treatments for species native to specific geographical regions are provided by Ochoa (1999), Contreras and Spooner (1999), and Spooner *et al.* (2004). In total, seven potato species are cultivated, but the cultivated potato of worldwide significance is *S. tuberosum* ssp. *tuberosum* and is the primary focus of this chapter. The taxonomy of the cultivated potato is summarized in Table 1.

Potato is a short-lived perennial species forming weak annual stems arising from underground

Series	<i>Tuberosa</i> (Rydb.) Hawkes
Species	<i>Solanum tuberosum</i> L.
Subspecies	<i>tuberosum</i>

tubers. As an agricultural commodity, potatoes are raised as an annual crop. Plants are small with individual stems 1 m or less in length. Plant habit ranges from compact to sprawling. Leaves are pinnately compound, arising alternately from the aboveground stems. The leaves may be lightly covered with fine trichomes. Potato flowers are clustered in a primary cymose inflorescence. Flowers are hypogynous and actinomorphic, with fused corollas with five lobes. Corolla color ranges from purple to pinkish to white. Fertilized flowers form spherical berries high in toxic glycoalkaloids. The berries carry small, flat, oval or kidney-shaped seeds that are yellowish to tan in color. The tuber is a carbohydrate storage structure arising from stolons (short underground stems or rhizomes). The prominent “eyes” of the tuber are actually clusters of axillary buds from which aboveground stems may arise. The tuber is both the primary commercial propagule and the organ of economic significance. Rubatzky and Yamaguchi (1997) provide detailed discussion of tuber morphology.

The basic chromosome number for potato species is 12. Cultivated potato is an autotetraploid ($2n = 4x = 48$ chromosomes) with tetravalent chromosome pairing during meiosis. Potato chromosomes are relatively small ($1\text{--}3.5\ \mu\text{M}$ at metaphase) and predominantly metacentric (Dong *et al.*, 2000). Mohanty *et al.* (2004) examined the karyotype of 30 different potato cultivars and breeding lines. Based on chromosome size and relative positioning of restrictions, the authors described five different chromosome morphologies. Individual genotypes differed considerably in overall karyotype, with several genotypes possessing unique combinations of the five basic chromosome types (Mohanty *et al.*, 2004), suggesting that morphology is not fully predictive of a given chromosome. Consistently, Dong *et al.* (2000) indicate that individual chromosomes cannot be reliably identified based solely on morphological features. Mok *et al.* (1974), Lee and Hanneman (1976), Pijnacker and Ferwerda (1984), and Wagenvoort *et al.* (1994) utilized Giemsa-banding patterns to identify specific potato chromosomes. Yeh and Peloquin (1965), Ramanna and Wagenvoort (1976), and Wagenvoort (1988) analyzed potato chromosomes at pachytene. At this stage, the patterns of heterochromatin and euchromatin can distinguish every chromosome, although several chromosomes have very similar banding patterns. The method has not found

widespread application owing to its technical difficulty and suitability only for analysis of diploid materials (Dong *et al.*, 2000). Dong *et al.* (2000) developed an entire set of chromosome-specific bacterial artificial chromosome (BAC) probes for fluorescent *in situ* hybridization (FISH). Mohanty *et al.* (2004) demonstrated that a single somatic cell (4C) varies in DNA content from 7.28 pg to 15.83 pg (picogram), a statistically significant difference. The authors attributed variation in DNA content to expansion or contraction of repetitive DNA in certain potato lineages (Mohanty *et al.*, 2004).

1.3 Economic Importance

For the 41-year period from 1965 to 2005, worldwide potato production increased by 19.26% from 270 913 502 t in 1965 to 323 102 918 t in 2005. Gains were most notable in Asia (Figure 1a), with production in China increasing 356.02% from 16 016 136 t in 1965 to 73 036 500 t in 2005 and production in India increasing 593.48% from 3 605 000 t in 1965 to 25 000 000 t in 2005. China and India currently lead world production (Table 2).

During the same 41-year period, there was a worldwide decrease in the number of hectares of potatoes grown of 12.95% from 21 391 391 ha in 1965 to 18 622 188 ha in 2005 (Figure 1b). Production area losses were greatest in European countries including Poland (a loss of 2 170 892 ha or 78.51%), Germany (a loss of 1 231 533 ha or 81.64%), France (a loss of 417 118 ha or 72.53%), Italy (a loss of 278 391 ha or 79.93%), and Spain (a loss of 275 095 ha or 74.67%). Production area gains were greatest in China (a gain of 2 700 266 ha or 158.72%), India (a gain of 971 000 ha or 226.34%), Bangladesh (a gain of 270 738 ha or 488.33%), Nigeria (a gain of 175 000 ha or 8750.00%), and Iran (a gain of 162 000 ha or 490.91%).

Between 1965 and 2005, worldwide average potato yield increased 37% from 126 646 hg ha^{-1} to 173 504 hg ha^{-1} (Figure 1c). Increases were most notable for North America and Central America (an increase in average yield of 75.69% from 214 954 hg ha^{-1} in 1965 to 377 659 hg ha^{-1} in 2005) and Oceania (an increase in average yield of 131.14% from 164 437 hg ha^{-1} in 1965 to 380 084 hg ha^{-1} in 2005). Other major production

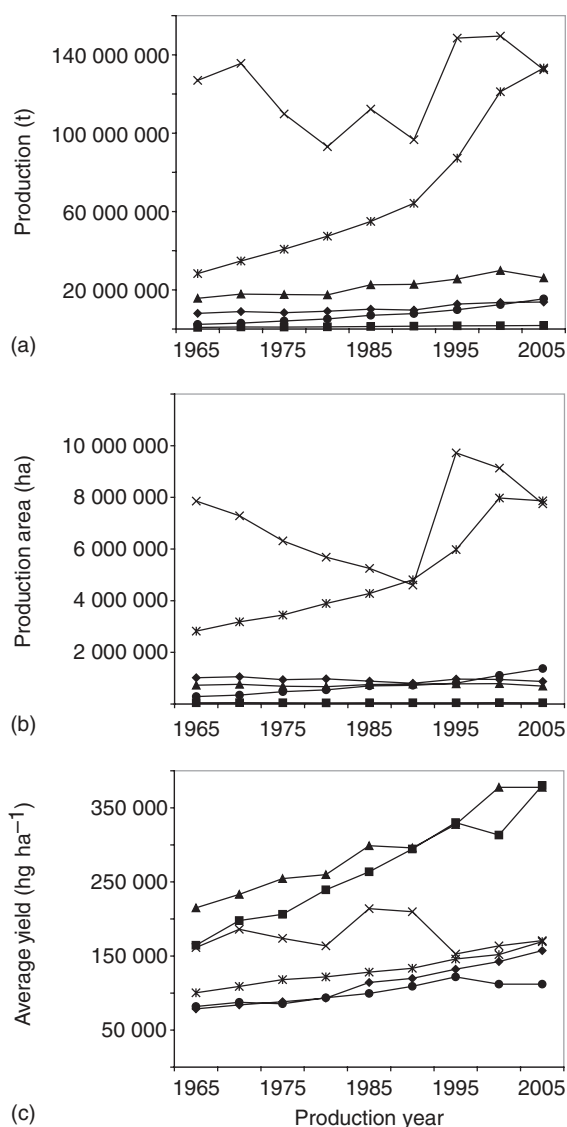

Figure 1 Trends in world potato production (1965–2005). Potato production statistics for Africa (●), Asia (*), Europe (x), North and Central America (▲), Oceania: Australia and New Zealand (■), and South America (◆) for the period 1965–2005. (a) Total annual potato production in metric tons. (b) Production area in ha. (c) Average yield in hg/ha. During the past four decades, total potato production in much of the world has remained constant. However, dramatic increases can be noted for Asia. European potato production during this period has fluctuated. Potato production area in much of the world has been steady with the exception of Asia, which has experienced large increases in potato production area, and Europe, where potato production area has fluctuated. Yield increases are particularly evident for North and Central America and Oceania, with only modest increases in potato yield noted in other regions of the world [Source: FAOSTAT.fao.org]

areas of the world experienced modest though predominantly steady gains in yield during this same period (Figure 1c).

Potato provides approximately 820 calories kg^{-1} , mostly in the form of carbohydrate, and has higher calorie per hectare yield potential than any grain (Rubatzky and Yamaguchi, 1997). Although potato provides only about 2.1 g of protein per 100 g fresh edible portion (Rubatzky and Yamaguchi, 1997), potato is a significant source of protein in the human diet in certain countries due to high consumption rates. In Belarus, average daily per capita consumption of potatoes in 2004 was 488.63 g, providing 15.17% of the United States Department of Agriculture (USDA) Recommended Daily Allowance for a 24 year's old (72 kg) male. Other top potato consuming nations in 2004 included Kyrgyzstan (385.59 g per day per capita), Rwanda (381.83 g per day per capita), Lithuania (373.76 g per day per capita), and Poland (373.73 g per day per capita) (FAOSTAT data 2004). Potato is a rich source of minerals, especially potassium (420 mg per 100 g fresh edible portion), and vitamin C (18 mg per 100 g fresh edible portion).

Potatoes are utilized in several ways. For culinary uses, tuber characteristics including water content, tuber shape and size, eye depth, sugar composition, and storability affect cultivar utility. As a direct food product, potatoes are commonly baked, boiled, or fried. Important processed potato foods include French fries and potato chips. Some South American communities still produce the freeze-dried potato product, *chuño*. Potatoes are the traditional source of the alcoholic vodka. Industrial uses for potato include the extraction of starch.

1.4 Traditional Breeding: Objectives, Tools and Strategies, and Achievements

Conventional strategies for potato breeding must address the complex genetic characteristics of this crop. Potato is a highly heterozygous polyploid with tetrasomic inheritance. Nonadditive gene interactions, e.g., intralocus (heterozygosity) and interlocus (epistasis) interactions, are important in determining potato phenotypes, thus offering the potential for exploiting heterosis in plant improvement since high levels of allelic diversity at loci of interest guarantee increased heterosis. The

^(a)Source: FAOSTAT^(b)Rank based on 2005 production statistics

more diverse the alleles are within a specific locus, the higher the heterozygosity and the greater the number of increased interlocus and epistatic interactions. Up to four different alleles are possible at each locus and maximum allelic diversity at a given locus A (e.g., $a_1a_2a_3a_4$) guarantees first, second, and third order interactions. Potato breeding has generally focused on genetic improvement at two ploidy and EBN levels: the tetraploid (4EBN) level and the diploid (2EBN) level.

Genetic improvement at the tetraploid (4EBN) level is mostly based on phenotypic recurrent selection, involving crosses between tetraploid varieties and/or advanced clones, and then field evaluation and selection. Most varieties currently used were derived using this breeding approach. The procedure starts with the selection of desirable parents, with breeders commonly targeting parents of diverse genetic origin to increase the chances of pyramiding different desired alleles in the progeny genotypes. Following crossing, various progeny tests, data on general and specific combining ability, and information derived from molecular markers are used to select the best progeny. Due to the high levels of heterozygosity, segregation of traits is expected in the F_1 generation. Tubers obtained from each selected F_1 clone are grown for further evaluations and to increase the number of seed tubers. During the next season clones are cultivated and screened in larger plots. After several years of clonal selection, superior clones are tested in different locations to estimate the genotype \times environment interaction.

While the genetic base of the cultivated potato is considered to be narrow (Mendoza and Haynes, 1974) and yield stasis exists within the potato germplasm of North America (Douches *et al.*, 1996), the potato has an extremely rich gene pool with seven cultivated and approximately 200 wild species (Spooner and Hijmans, 2001). To broaden the genetic base of the cultivated potato and introduce new traits, North and South American potato species have been used as sources of new genes (Haynes, 1972; Hermundstad and Peloquin, 1985). To exploit the wealth in allelic diversity of these tuber and nontuber bearing species and to take advantage of disomic rather than tetrasomic inheritance, several breeding programs have focused on genetic improvement at the diploid (2EBN) level. These programs make use of sexual hybridization between $2x$ (2EBN) species and

$2x$ (2EBN) *S. tuberosum* haploids. Haploid-species hybrids are selected for traits of interest and also for a propensity for $2n$ gamete production. In Poland, haploid-species hybrids with multiple resistances and tuber qualities are developed and used in $4x \times 2x$ crossing schemes to produce parental lines and cultivars. The same holds true in Italy, Great Britain, Netherlands, and other European Union (EU) countries. These hybrids are then employed in sexual polyploidization crossing schemes with potato ($4x$ (4EBN)) to re-establish the tetraploid level of the cultivated *S. tuberosum*. $2n$ gametes not only allow the restoration of the tetraploid level, but also permit the transmission of large amounts of the parental heterozygosity and epistatic interactions without disruption by recombination (Peloquin *et al.*, 1999). Exploitation of $2n$ gametes also allows the development of various breeding schemes based on the manipulation of whole chromosome sets, permitting gene flow through interploid and bridge crosses (reviewed in Carputo and Barone, 2005).

The development and marketing of new varieties in Europe is generally the responsibility of private breeding companies. Public programs have been mostly discontinued and currently public institutions are involved in variety release only in a few countries (mainly in Eastern Europe). By contrast, in the United States, potato breeding is the concern of the public sector and only a few companies develop new varieties. As with many other crops, both in Europe and in the United States, traditional potato breeding is not concerned with only one objective, but with many. Priorities include resistance to biotic and abiotic stresses (diseases, pests, drought, heat, and cold) and quality requirements for either table use or processing (tuber yield, shape and size, dry matter and sugar content, sensitivity to cold sweetening, discoloration, bruising, and starch characteristics). Tarn *et al.* (1992) have identified 18 traits related to fresh and processing uses, 17 pathogen and six pest resistance traits, and numerous agronomic traits that need to be considered in a potato breeding program.

Resistance to late blight, caused by the oomycete *Phytophthora infestans*, is still a primary target in terms of biotic stresses. The disease is characterized by haulm destruction and decay of the tubers. Worldwide research has been brought together by the Global Initiative on Late

Blight (GILB), a network of researchers and technology developers from more than 70 countries. Europe, in particular, has a long history of resistance breeding against *P. infestans* and the European Union has funded the construction of a database (<http://www.Eucablight.com>) to provide tools for investigating variation in both the host and the pathogen. In the United States, due to conducive climatic conditions and growing practices, the Midwestern states are particularly vulnerable. Consistently, during recent years in North America, potato late blight has re-emerged as the most important pathogen of the potato crop. The US-8 genotype of *P. infestans*, the predominant genotype present in the United States, is characterized by reduced sensitivity to metalaxyl and the A2 mating type (Deahl *et al.*, 1993). One aspect of late blight disease management in the field is the use of resistant cultivars. It is important to draw upon many germplasm resources to develop a broad genetic base and identify differences in expression of single components of field resistance (i.e., resistance to infection, spread, and sporulation), then hybridize according to complementary components. Concurrently, the high standards demanded by the industry and consumers for yield, maturity, class, quality, and multiple resistances must be met.

The Colorado potato beetle, *Leptinotarsa decemlineata* is one of the most economically significant pests of potato in northern latitudes. The Colorado potato beetle led to the first large-scale use of insecticides in 1864 (Gauthier *et al.*, 1981) and insecticides remain the primary means of Colorado potato beetle control (Casagrande, 1987). About 1.3 million lbs of active ingredients of the insecticides are applied to potato crops to control Colorado potato beetle in the top eight potato-producing US states (Wiese *et al.*, 1998). However, the Colorado potato beetle has shown a remarkable ability to develop resistance to every insecticide used for its control (Bishop and Grafius, 1996) and has done so at an increasingly fast rate (Heim *et al.*, 1990; Ioannidis *et al.*, 1991). Resistance to nematodes is also another important breeding target. The potato is a major host for potato cyst nematodes *Globodera pallida* and *Globodera rostochiensis* and for root-knot nematodes (*Meloidogyne* spp.). In Europe, the availability of varieties resistant to *G. rostochiensis* has accentuated

the presence of *G. pallida*, and therefore breeding efforts are being directed toward the development of genotypes resistant to this cyst nematode.

Of the bacterial diseases, *Streptomyces scabies* is one of the major pathogens that infect potato and cause scab. The pathogen produces necrotic, corky-textured lesions on the outer surface of the potato. The lesions can vary in their appearance as being raised, surface, or pitted. Chip processors consider pitted lesions a chip defect because the pit will be apparent in the chip. Surface and raised lesions present less of a problem as potatoes are peeled before they are chipped, thereby removing the lesions. Even so, since the marketplace for potatoes is quality driven, the presence of scab lesions, especially those that are pitted, on the outer surface of the potato for both table and processing varieties significantly lessen their marketability. The best and most reliable solution to scab is through the use of host resistance (Ross, 1986; Loria *et al.*, 1997).

In recent years, in part due to the growing market for fresh, prepacked potatoes and to the expansion of EU to include eastern countries, resistance to other pests including *Colletotrichum coccodes*, *Rhizoctonia solani*, *Verticillium* spp., *Clavibacter michiganensis*, and *Dickeya dadantii* (formerly *Erwinia chrysanthemi*) have also become major objectives for European potato breeders.

Among abiotic stresses, resistance to low temperatures is deemed very important in the Mediterranean area. Here the potato is grown "off-season" (starting from November), in a cycle that is much earlier than the typical spring-summer cycle. Due to the lack of resistant varieties, "off-season" production can be seriously damaged by frost events.

Breeding objectives related to quality requirements for processed potatoes are quite different from those for fresh use. The former are more precisely defined and are mainly related to dry matter content, level of reducing sugars after harvest, starch quality and, to some extent, tuber shape and size. The latter falls more in the category of "external traits" (e.g., skin and flesh color, eye depth), even though eating quality traits, such as after-cooking blackening are also important. A recent treatment by Renatus (2005) on the European potato trade pointed out that breeders need to consider that the fresh market is now segmented into two main categories. The first

includes the standard merchandise at a discount price level, where breeders are required to provide cost efficient, high yielding multiuse varieties. The second segment comprises the visually appealing high priced top quality potatoes. This high-end segment requires the release of varieties with superior taste and increased nutritional value. Due to growing awareness of the role of food quality on human health, new objectives of potato breeding have arisen in the last few years. Following discussion on acrylamide accumulation in fried products (Motttram *et al.*, 2002), a recent target for potato breeders is the development of varieties that do not accumulate asparagine, the precursor of acrylamide. Equally important has become the possibility to have varieties with long dormancy, in order to avoid the use of chemical sprout suppressants. Recent work to improve potato nutritional quality has also focused on modifying carotenoid, anthocyanin, or antioxidant content, as well as exploring the natural variation for important endogenous nutrients, such as vitamin C (Lu *et al.*, 2001; Brown *et al.*, 2003; Love *et al.*, 2004; Reyes *et al.*, 2004). Thus far, nutritional improvement in potato has been limited to designing potatoes for delivery of unique carotenoids shown to reduce the incidence of particular diseases, or increasing general antioxidant levels. For example, overexpression of phytoene synthase was shown to result in 19-fold higher levels of lutein, as well as higher β -carotene levels (Ducreux *et al.*, 2005), zeaxanthin contents were increased up to 130-fold through disruption of zeaxanthin catabolism (Römer *et al.*, 2002), and accumulation of astaxanthin was achieved through expression of a microbial β -carotene ketolase gene (Morris *et al.*, 2006). Crowell *et al.* (2008) overexpressed p-hydroxyphenylpyruvate dioxygenase (HPPD) and homogentisate phytyltransferase (HPT) to assess their impact on vitamin E accumulation in potato tubers. Overexpression of *At-HPPD* resulted in a 2.7-fold increase in α -tocopherol, while overexpression of *At-HPT* doubled the levels.

1.5 Limitations of Conventional Breeding and Rationale for Transgenic Breeding

Conventional potato breeding approaches have led to the development of new varieties suitable

for various uses. Following parental genotype selection and crosses, progeny are phenotypically evaluated over several years and sites. It may take a number of years (up to 15) to develop a new variety using these approaches. In the case of conventional breeding conducted at the tetraploid level, the tetrasomic inheritance of the potato and its high level of heterozygosity require that large numbers of progeny (i.e., large numbers of individual F_1 seedlings) must be evaluated to find useful segregants. Difficulties are also presented by the polygenic control of many traits of interest. Since they are not inherited in a simple Mendelian fashion, phenotypes cannot be grouped into a small number of easily distinguished classes, and the genotype \times environment interaction is usually high.

Breeding schemes to access genes possessed by wild germplasm require various cycles of backcrosses, evaluation, and selection to eliminate undesirable traits derived from the wild. This process is often expensive in terms of costs, time, and resources. In addition, there are some reproductive aspects of the potato (e.g., nuclear-cytoplasmic male-sterility and incompatibility barriers) that may hamper breeding when interspecific/interploidy hybridization is used to expand the cultivated gene pool. The use of molecular markers linked to target genes or quantitative trait loci (QTLs) may allow faster and more efficient identification of superior genotypes. However, despite its potential, relatively few examples of molecular marker-assisted selection are reported in potato. According to Mullins *et al.* (2006) this is mainly due to the outbreeding, tetraploid nature of the cultivated potato and to the fact that most traits are quantitatively inherited, with a large genotype \times environment interaction.

Transgenic approaches can help to overcome some of the limitations of conventional breeding strategies. It should be pointed out, however, that the transgenic approach is not, as often presented, simply a faster and more precise alternative to classical breeding. Rather, it is an additional, complementary way of accessing genetic diversity for genotype improvement. Like other breeding approaches, the creation and evaluation of transgenic potato lines can be time consuming and costly. In effect, transgenic approaches and conventional breeding are parallel processes in that variety development through a transgenic

approach may require that hundreds of individuals be screened to identify those possessing the most desirable expression of the transgene. Similarly, in conventional breeding, large populations with high genotypic and phenotypic variability are evaluated. Bradford *et al.* (2005) reviewed how genetic modifications caused by conventional breeding can be considered analogous to transgenic events. Mutation breeding, for example, is based on random genetic changes and selection is mainly based on the phenotype, without any knowledge of the underlying genetic cause. Wide crosses and ploidy manipulations produce various pleiotropic effects on gene structure and trait expression. Loss-of-function alleles, transposon and retroviral movements are additional events common to conventional and transgenic breeding.

The use of transgenic approaches, combined with conventional breeding, is emerging as a balanced approach to develop improved potato varieties with long- and short-term breeding strategies. Transgenic potato was first reported in 1986 (An *et al.*, 1986; Shahin and Simpson, 1986). These were created via *Agrobacterium tumefaciens*-mediated transformation. Since that time, various vectors and approaches have been used to insert transgenes into the potato genome. Of particular promise, the development of particle bombardment technologies for potato (Romano *et al.*, 2001) offers the potential for the simultaneous transfer of multiple genes. Also noteworthy is the possibility to perform plastid transformation (Nguyen *et al.*, 2005), which can be crucial for producing vaccines in potato plants. The use of non-*Agrobacterium* bacteria (e.g., *Rhizobium* and *Mesorhizobium*), methods for gene silencing, and plant-derived vectors hold promise for improving potato transformation methods and approaches (see Section 2). In potato, the transgenic approach seems particularly feasible to access genes from wild species. Many of the wild potato species possess an enormous wealth of noteworthy genes whose introgression through conventional breeding may have various limitations in terms of time and resources. *Agrobacterium*-mediated transformation, for example, allowed the introgression from the incongruent species *Solanum bulbocastanum* of genes conferring resistance to *P. infestans* (Song *et al.*, 2003a; Van Der Vossen *et al.*, 2003, 2005). The transgenic

approach may also circumvent genetic problems related to backcrossing including reduction in heterotic effect and loss of desired phenotypic characteristics through meiotic reassortment.

The transgenic approach is probably the best system to exploit recent advances in the field of structural and functional potato genomics. These studies have contributed to an understanding of the complex multistep processes related to potato quality and to elucidation of the genetics of traits of interest. For example, the biosynthetic networks involved in carbohydrate metabolism, vitamin C, and glycoalkaloid production have been described, and the genetic basis of quality traits such as starch content, chip color, anthocyanin pigmentation, and tuber shape have been determined. Subsequently, genes controlling expression of many important traits have been isolated. The transfer of these genes as transgenes into potato genotypes of interest can improve cultivars lacking in quality-related traits or can lead to production of novel metabolites of industrial, pharmaceutical, and veterinarian use.

2. DEVELOPMENT OF TRANSGENIC POTATOES

2.1 Donor Genes

Research efforts in recent years have led to the genetic characterization, mapping, and cloning of several genes of agricultural relevance to potato. Of particular note are genes imparting improved resistance to diseases, pests, and abiotic stresses, better processing qualities, and novel industrial characteristics. These genes originate from a variety of organisms, including cultivated and wild potato species, nonpotato plant species, and even bacteria and viruses. Genes cloned from potato species and showing particular promise for improvement of cultivated potato through transgenic technologies are summarized in Table 3. De Jong (2005) reviewed important molecular approaches used to clone potato genes, including map-based cloning and candidate gene identification. The identification and cloning of agriculturally relevant genes opens the door to improvement of important potato cultivars using transgenic approaches.

2.1.1 Transgenes for resistance to biotic and abiotic stresses

Potato is host to more than 60 diseases of current economic significance (Stevenson *et al.*, 2001) and commercial potato production in most parts of the world relies heavily upon chemical inputs, including fungicides. Genetic resistance to significant potato diseases offers the potential to reduce grower costs and environmental risks associated with chemical inputs. Chief among potato diseases worldwide is late blight, a disease of both foliage and tuber caused by the oomycete *P. infestans*. Late blight has a notorious past for its role in the Irish Potato Famine of the mid 1800s, during which a million people starved to death and a million more emigrated from Europe to the United States. Today, the disease causes an estimated annual loss of US\$5 billion worldwide, both through yield losses of potato and tomato and through increased production costs associated with chemical controls (Kamoun, 2001). Wild potato species, especially those indigenous to central Mexico and certain regions of the Andes, areas ideal for late blight epidemics, are sources of resistance genes for improvement of cultivated potato. Not surprisingly, considerable research effort has been devoted to the molecular cloning of resistance genes imparting late blight resistance, with particular emphasis on wild potato species.

Among the earliest examples of resistance breeding, the Mexican species *Solanum demissum* was crossed with potato nearly 100 years ago (Salaman, 1911; Umaerus and Umaerus, 1994). Eleven late blight resistance genes have been genetically described from this species (Black and Gallegly, 1957; Malcolmson and Black, 1966; Umaerus and Umaerus, 1994). These genes are referred to as the “R series” and are numbered from *R1* to *R11*. Each is associated with a pathogen race-specific, hypersensitive response (HR) characterized by controlled cell death surrounding the site of infection. Several have been mapped: *R1* on chromosome 5 (Leonards-Schippers *et al.*, 1992), *R2* on chromosome 4 (Li *et al.*, 1998), and *R3*, *R6*, and *R7* on chromosome 11 (El-Kharbotly *et al.*, 1996). Initially promising in the agricultural setting, these genes proved to be of short durability as the pathogen quickly circumvented their defenses (Toxopeus, 1956; Black and Gallegly, 1957).

Using BAC-based positional cloning in combination with a candidate gene approach, Ballvora *et al.* (2002) reported the cloning of *R1*. The gene was first fine mapped using populations generated from diploid *S. tuberosum* lines into which the *S. demissum* *R1* gene was introgressed (Gebhardt *et al.*, 1989; Leonards-Schippers *et al.*, 1992; Meksem *et al.*, 1995). Once corresponding BAC clones were isolated, BAC-end sequence analysis revealed similarity to a previously cloned plant disease resistance gene. Subsequent further BAC isolation and subcloning into binary cosmid vector pCDL04541 led the authors to a 10 kb fragment containing the candidate gene along with 2 kb upstream and 4 kb downstream of the predicted coding region. The binary cosmid vector pCDL04541 was derived from vector SLJ1711 (Jones *et al.*, 1992) by the addition of a cos site for lambda bacteriophage packaging. In turn, SLJ1711 was derived from the broad host range vector pRK290 (Ditta *et al.*, 1980) by the addition of an insert that carries the *NPTII* gene for resistance to the antibiotic kanamycin driven by the constitutive cauliflower mosaic virus promoter, CaMV 35S and a polylinker site associated with dark Bluescript (dBS) blue/white selection. pCDL04541, like pRK290, also carries a gene for resistance to the antibiotic tetracycline. pCDL04541 has been widely used in plant transformation research. By transforming late blight susceptible potato cultivar Désirée with the pCDL04541 vector containing a 10 kb genomic insert, Ballvora *et al.* (2002) demonstrated that the late blight resistance gene *R1* including the endogenous promoter and any downstream elements was carried in the subclone. *R1* was the first late blight resistance gene to be cloned.

S. demissum is also source of the late blight resistance gene *R3a*. The locus maps to a resistance gene “hot spot” on chromosome 11. Using fine-mapping and functional testing, Huang *et al.* (2004) demonstrated that the previously defined *R3* locus is actually two tightly linked loci with distinct specificities, *R3a* and *R3b*. Subsequently, the authors reported the cloning of *R3a* (Huang *et al.*, 2005). *R3a* was cloned using a comparative genomics approach. Significantly, microsynteny was noted between the potato *R3a* locus (harboring the late blight resistance allele derived from *S. demissum*) and the corresponding

region in tomato. The tomato region encompassed a portion of the *I2* gene complex responsible for resistance to *Fusarium* wilt. Huang *et al.* (2005) screened potato BAC DNA pools encompassing 0.05 genome equivalents for the presence of markers mapped in close proximity to *R3a*. The same pools were also screened for the presence of *I2*-like sequences using primers developed from tomato sequence. In total, the authors identified 11 overlapping BAC clones encompassing a 700 kb genomic region that included both *R3a* markers and *I2*-like sequences. Two BACs were sequenced, revealing five *I2*-like sequences, each a candidate for the functional *R3a* locus. The candidate genes were subcloned as 10 kb fragments into the pBINPLUS vector. pBINPLUS was developed from pBIN19 (van Engelen *et al.*, 1995). The vector carries the *NPTII* gene for resistance to the antibiotic tetramycin and the *lacZ'* gene for blue/white selection. Each *R3a* candidate gene cloned into the pBINPLUS vector included 2–3 kb of genomic sequence before and after the putative transcript, presumably incorporating the endogenous promoter and downstream elements. Transformation revealed that one of the candidate genes imparted late blight resistance to susceptible potato cultivars (Huang *et al.*, 2005).

Other *S. demissum* late blight resistance genes are also likely candidates for cloning in the near future, including the *R7* gene of chromosome 11. While isolation of *R1-R11* is historically and scientifically significant, the early defeat of these genes in the field suggests they may be of limited agricultural application as transgenes. In contrast, the Mexican diploid wild potato *S. bulbocastanum* is a source of broad-spectrum late blight resistance genes that may be more durable in an agricultural setting. *S. bulbocastanum* has long been recognized as a source of late blight resistance (Reddick, 1939; Neiderhauser and Mills, 1953; Graham *et al.*, 1959). However, direct sexual crosses between potato and *S. bulbocastanum* have never been reported. Researchers have attempted to access resistance from *S. bulbocastanum* using a series of bridge crosses (Hermesen and Ramanna, 1973) or somatic hybridization (Helgeson *et al.*, 1998) approaches that incorporate undesirable characteristics along with resistance, complicating cultivar development. Late blight resistance in *S. bulbocastanum* is functionally distinct from that of *S. demissum*. Examining somatic hybrid

(cultivated potato + *S. bulbocastanum*)-derived lines in the Toluca Valley, Helgeson *et al.* (1998) concluded resistance from *S. bulbocastanum* lacks pathogen race specificity and a discernible HR phenotype. Instead, resistance from *S. bulbocastanum* suppresses but does not prevent disease development (Helgeson *et al.*, 1998). Suppression of the rate of symptom development may alone impart agriculturally meaningful, durable resistance.

The first late blight resistance gene cloned from *S. bulbocastanum* was *RB* (Song *et al.*, 2003b), also referred to as *Rpi-blb1* (Van Der Vossen *et al.*, 2003). *RB* was first mapped to *S. bulbocastanum* chromosome 8 using a somatic hybrid (potato + *S. bulbocastanum*)-derived mapping population (Naess *et al.*, 2000). Random amplified polymorphic DNA (RAPD) and restriction fragment length polymorphism (RFLP) markers associated with *RB* were starting points for BAC-based positional cloning while concomitant fine-mapping using BAC-end-derived markers further defined the resistance region genetically (Bradeen *et al.*, 2003). A single BAC clone encompassing the resistance region was sequenced, revealing a cluster of four putative genes belonging to the nucleotide binding site-leucine rich repeat (NBS-LRR) family. Approximately 75% of all cloned plant disease resistance genes belong to this family and the four *S. bulbocastanum* sequences were each considered as candidates for the functional *RB* gene. The *S. bulbocastanum* genotype used to map *RB* and for BAC library construction was heterozygous for *RB*, with one haplotype carrying an allele at the *RB* locus for late blight resistance and the other haplotype carrying an allele at the *RB* locus for late blight susceptibility. The BAC clone sequenced by Song *et al.* (2003b) was shown through genetic mapping to carry the susceptibility allele; the resistance haplotype was never recovered from the 12× genome equivalents BAC library, despite exhaustive library screening. This was later explained by instability of BAC clones carrying the *RB* resistance allele (Song *et al.*, 2003a) and necessitated that positional cloning be supplemented with a long-range (LR)-polymerase chain reaction (PCR) approach (Song *et al.*, 2003b). Briefly, genomic DNA from a late blight resistant *S. bulbocastanum* genotype was used as a template for LR-PCR amplification of each of the candidate genes using primers designed

from BAC sequence from the susceptibility allele haplotype. To ensure recovery of the endogenous promoter and terminator elements, LR-PCR primers were designed such that the amplicons would encompass several kilobytes of genomic sequence upstream and downstream of the putative transcripts. Each of the four candidate genes was targeted using this approach and in each case, the amplicon included DNA copies derived from both *RB* haplotypes (Song *et al.*, 2003b). The LR-PCR amplicons were cloned into vector pCLD04541. Transformation of the late blight susceptible potato cultivar Katahdin revealed that one of the candidate genes was *RB*. *RB* imparts a broad-spectrum, nonrace-specific resistance to transformed potato and tomato lines.

A second late blight resistance gene, *Rpi-blb2*, has also been cloned from *S. bulbocastanum* (Van Der Vossen *et al.*, 2005). The gene was first mapped to a single region of *S. bulbocastanum* chromosome 6 in tetraploid populations derived from interspecific crosses involving four different species. Subsequent fine-mapping was done in a diploid *S. bulbocastanum* population and involved the use of a resistance gene homolog-fingerprinting technique. Results of these efforts suggested that *Rpi-blb2* shared DNA sequence homology to the tomato *Mi-1* gene. BAC-based positional cloning ensued. The authors ultimately developed a BAC contig encompassing approximately 12 *Mi-1* like sequences and the entire genetically defined resistance region. A subclone library of approximately 10 kb fragments was generated from each BAC clone using vector pBINPLUS. Subclones were subjected to a PCR screen and subclones containing nine different *Mi-1* like candidate genes were identified. Transformation of susceptible potato cultivars revealed that one of the candidate genes imparted late blight resistance and was, therefore, *Rpi-blb2*. *Rpi-blb2*, like *RB*, imparts broad-spectrum, nonrace-specific late blight resistance.

S. bulbocastanum is a likely source of other late blight resistance genes (Park *et al.*, 2005) that may be of agricultural significance. Other potato species including *Solanum berthaultii* (Ewing *et al.*, 2000; Rauscher *et al.*, 2006), *Solanum mochiquense* (Smilde *et al.*, 2005), *Solanum phureja* (Sliwka *et al.*, 2006), *Solanum pinnatisectum* (Kuhl *et al.*, 2001; Chen *et al.*, 2003), and *Solanum polyadenium* (Bradeen, unpublished results) are sources of novel

late blight resistance genes that may be future subjects of cloning efforts.

Genes imparting late blight resistance have not been the only targets for molecular biologists. Several genes imparting resistance to other significant potato disease have also been cloned. Two genes, the *Rx1* gene for resistance to potato virus X and the *Gpa2* gene for resistance to the potato cyst nematode (*G. pallida*) were cloned from a common region of chromosome 12 of *S. tuberosum* subsp. *andigena* (Bendahmane *et al.*, 1999; Kanyuka *et al.*, 1999; Rouppe Van Der Voort *et al.*, 1999; Van Der Vossen *et al.*, 2000). The genes were cloned using a BAC-based positional cloning approach that included fine-mapping of the traits in several different populations (Rouppe Van Der Voort *et al.*, 1999). *Rx1* was cloned first (Bendahmane *et al.*, 1999). The authors verified that a single BAC clone encompassed the genetically defined *Rx1* region through genetic mapping (Kanyuka *et al.*, 1999) and functionally confirmed this by biolistic-mediated transient expression assays of the BAC clone and BAC subclones in potato and the related *Nicotiana benthamiana* (Bendahmane *et al.*, 1999). Ultimately, the functional *Rx1* transcript was shown to reside within an 11 kb BAC subclone fragment. A transgene for stable integration was developed by subcloning an 18 kb BAC fragment (which encompassed the 11 kb fragment and provided enough additional genomic sequence to ensure recovery of native regulatory regions) into the binary vector pSLJ7292. pSLJ7292 was developed from vector pRK290 and carries the *NPTI* gene for kanamycin resistance and the *Tet* gene for tetracycline resistance. Bendahmane *et al.* (1999) transformed potato virus X-susceptible potato cultivar Maris Bard using the putative *Rx1* transgene. Subsequent functional tests confirmed resistance of transgenic lines. To isolate *Gpa2*, four BAC clones spanning the genetically defined region were sequenced (Van Der Vossen *et al.*, 2000). Four NBS-LRR gene copies were identified, one of which corresponded to *Rx1*. The remaining three sequences were considered as candidates for *Gpa2*. Subclones containing 6.5–11 kb BAC fragments encompassing the candidate genes were inserted into vector pBINPLUS. Each included at least 2 kb of genomic sequence before and 0.5 kb of genomic sequence after the putative transcript. Transformation of the nematode-susceptible potato line V and phenotypic testing

confirmed that a 10.3 kb genomic fragment imparted resistance and thus encoded *Gpa2*. Importantly, *Gpa2* and *Rx1* share greater than 88% amino acid identity, indicating that highly similar genes may condition resistance to very different pathogens (Van Der Vossen *et al.*, 2000).

Paal *et al.* (2004) used a candidate gene approach to clone a second nematode resistance gene. *Gro1* confers resistance to the root cyst nematode (*G. rostochiensis*) and originated from the wild potato *Solanum spegazzinii* but was introgressed into cultivated potato via sexual crosses. First, resistance was mapped to a 1.4 cM region of potato chromosome 7 (Barone *et al.*, 1990; Ballvora *et al.*, 1995). Next, Leister *et al.* (1996) used degenerate primer PCR targeting conserved motifs common to NBS-LRR genes to amplify fragments from the potato genome. The authors identified two resistance genelike (RGL) sequences that co-segregated with *Gro1* and defined a multigene family. Paal *et al.* (2004) used restriction fragment length patterns generated from diverse root cyst nematode resistant and susceptible genotypes to identify a series of candidate genes for *Gro1* based on sequence similarity to RGL markers generated by Leister *et al.* (1996). Various molecular approaches including fine-mapping and segregation analyses allowed the authors to narrow the candidate gene pool down to three gene copies. BAC clones corresponding to these candidate genes were identified. Subclones for each, ranging in size from 10.5 kb to 22.0 kb and including 2.3 kb to 4.0 kb before and 1.1 kb to 3.4 kb after the putative transcript, were generated in vector pCLD04541. Transformation of susceptible cultivar Desiree revealed that one of the candidate genes imparted nematode resistance.

In addition to disease resistance genes isolated from potato species, several resistance genes with relevance to potato have been isolated from other plant species. Especially relevant examples cloned from tomato include the *Cf-9* gene conferring resistance to *Cladosporium fulvum* (Jones *et al.*, 1994), *Hero*, conferring resistance to *G. rostochiensis* (Ernst *et al.*, 2002), *I2*, conferring resistance to *Fusarium oxysporum* (Ori *et al.*, 1997), *Mi-1*, conferring resistance to root-knot nematode (*Meloidogyne javanica*) (Milligan *et al.*, 1998) and the insect whitefly (*Bemisia tabaci*) (Nombela *et al.*, 2003), the *Prf* (Salmeron *et al.*, 1996) and *Pto* (Martin *et al.*, 1993) loci conferring resistance

against *Pseudomonas syringae*, *Sw5d*, conferring resistance to tomato spotted wilt virus (Brommonschenkel *et al.*, 2000), and *Ve1* and *Ve2*, closely linked genes conferring resistance against *Verticillium albo-atrum* (Kawchuk *et al.*, 2001). These tomato genes have been cloned using a variety of methods, especially positional cloning facilitated by fine-scale molecular mapping, and candidate gene approaches. The close genetic relationship between potato and tomato suggests that these tomato disease resistance genes may be of agricultural relevance to both species. Additionally, functional potato homologs of these genes may be identified. A functional potato homolog of the tomato *Ve1* gene, *StVe1*, has been reported (Simko *et al.*, 2004) and *Rpi-blb2*, cloned from *S. bulbocastanum*, is a functional homolog of the tomato *Mi-1* gene (Van Der Vossen *et al.*, 2005). Improvement of disease resistance in potato using transgenes from more distantly related plants species also shows promise (reviewed in Mullins *et al.*, 2006).

Researchers have also utilized transgenic strategies to limit the impact of Colorado potato beetle on potato production. *Bacillus thuringiensis* (*Bt*) is an aerobic, gram-positive, soil bacterium that accumulates high levels of insecticidal crystal proteins during sporulation (McGaughey and Whalon, 1992; Barton and Miller, 1993). The *Bt* bacteria produce insecticidal crystal proteins that are encoded by single genes. To date, more than 300 *Bt* proteins associated with insecticidal crystals have been identified. These have been classified into 51 groups based on amino acid homologies (Ruiz de Escudero *et al.*, 2006). Most of these proteins are known as Cry proteins and many have been successfully used in biological insecticides. Cry proteins are effective against a variety of insect species, including the Colorado potato beetle. Schnepf *et al.* (1998) reviewed the salient molecular properties and modes of action of insecticidal *Bt* crystal proteins. Several of the insecticidal *Bt* genes have also been used as transgenes and the generation of transgenic plants may be the most effective means to deliver *Bt*-based insecticides.

Relative to those of most plant species, the *Bt* genome is A-T rich and *Bt* genes used directly as transgenes in plants can perform poorly due to nonplant codon bias and the introduction of unintentional splice sites, polyadenylation sites, messenger-RNA (mRNA) degradation sites, and transcription

termination sites (Schnepf *et al.*, 1998). Accordingly, researchers have modified native *Bt* genes to more closely mimic plant genes. The efficacy of codon-modified *Bt* genes such as *Bt-cry1* and *Bt-cry3A* has been demonstrated to be greater than the wild type *Bt* genes in crop plants (Perlak *et al.*, 1991; Wünn *et al.*, 1996). Adang *et al.* (1993) transformed potato with a *Bt-cry3A* gene modified to reflect dicot codon bias. The transgene consisted of the 1.8 kb modified coding region under the control of the Mac promoter, a chimeric promoter constructed from the CaMV 35S promoter and the mannopine synthetase (*mas*) promoter. The transgene also included a *mas*-derived termination signal. The resulting cassette was cloned into the binary vector pCGN1558, which carries the *NPT* gene for kanamycin resistance (McBride and Summerfelt, 1990). Analysis of the resulting transgenic potatoes revealed that 58 of 63 lines displayed enhanced tolerance to feeding by Colorado potato beetle (Adang *et al.*, 1993). Perlak *et al.* (1993) also modified the *Bt-cry3A* gene, without modifying the resultant amino acid sequence, to enhance expression in plants. Cloned into vector pMON10547 and driven by the CaMV 35S promoter, the transgene imparted Colorado potato beetle resistance to the susceptible cultivar Russet Burbank. The transgene was effective in both the laboratory and the field and had no apparent impact on agronomic traits (Perlak *et al.*, 1993). Other *Bt-cry3A* potato lines have been developed in the public sector that combine *Bt-cry3A* with natural resistance (Coombs *et al.*, 2003). NewLeaf[®] potatoes (from Monsanto Technology LLC) containing a *Bt-cry3A* transgene were registered and made available for commercial production from 1995–2001. NewLeaf potatoes were marketed under the name “NatureMark”. First available for cv. Russet Burbank, the NewLeaf technology was later applied to cvs. Atlantic and Superior. NewLeaf Plus[®] potatoes followed, combining *Bt-cry3A*-mediated resistance to Colorado potato beetle and resistance to potato leaf roll virus (PLRV) conferred, presumably through RNA silencing, by transformation with the PLRV replicase gene (Lawson *et al.*, 2001). A third NatureMark product, NewLeaf Y combined *Bt-cry3A*-mediated resistance to Colorado potato beetle and resistance to potato virus Y (PVY). NatureMark products were eventually taken off

the market because of processors’ concerns about genetically modified foods in international sales.

A key tactic to resistance management is the development of alternative modes of action in the *Bt*-transgenic potato. No single form of resistance, either genetically engineered or classically bred, is likely to provide long-term control to highly adaptable insects, like the Colorado potato beetle, particularly if other mortality factors, such as crop rotation or biological control, are not included in the management system. More durable strategies than single factor *Bt*-based host plant resistance must be developed.

Minimizing an insect’s access to biotin using genetic engineering approaches may compliment *Bt*-mediated crop protection. Biotin is an essential co-enzyme required for all insect growth and development. Without this co-enzyme, an insect’s growth is severely stunted, eventually leading to death (Markwick *et al.*, 2001). Avidin is a protein found in chicken egg whites; this protein protects the chicken embryo by sequestering biotin from disease-causing organisms (Hood *et al.*, 1997). The gene for avidin production has been cloned (Hood *et al.*, 1997). The avidin gene has also been inserted and expressed in a few crops, including maize and tobacco and has demonstrated resistance to a wide spectrum of insect pests (Kramer *et al.*, 2000; Markwick *et al.*, 2001; Burgess *et al.*, 2002). All insects need biotin; therefore, avidin is a more broad-spectrum toxin than *Bt* crystal proteins. Avidin could be used not only to delay resistance of Colorado potato beetle to *Bt-cry3A*, but it may also be useful to control other pests such as potato leafhopper, aphids, and European corn borer.

Another approach to delaying or preventing an insect’s resistance to *Bt* insecticidal proteins is to combine *Bt* transgenes with insect resistance genes of different modes of action acquired through traditional breeding strategies. Host plant resistance management combining genetically engineered resistance with traditionally bred host plant resistance has the potential to be much more sustainable and easily implemented. Combining host plant resistance factors as a resistance management strategy does not require grower cooperation or regulatory monitoring or enforcement. Incorporation of host plant resistance into an integrated pest management system involving multiple biological, cultural, and

chemical controls will further increase the sustainability of a pest management system.

Glycoalkaloids are compounds expressed in the leaves and tubers of certain potato species that deter insect feeding. When expressed at high levels in the tubers, glycoalkaloids may be toxic to mammals. The wild potato *Solanum chacoense* produces novel glycoalkaloids known as leptines in the leaves but not the tubers (Sinden *et al.*, 1986a, b; Sanford *et al.*, 1997). It may be possible to incorporate high foliar leptine production from *S. chacoense* into cultivated potato using sexual crosses and somatic hybridization (Cheng *et al.*, 1995; Veilleux and Miller, 1998; Rangarajan *et al.*, 2000). Studies by Cooper *et al.* (2004) suggests that the mode of action of leptines may be different from that of *Bt*, leading to the hypothesis that pyramiding *Bt* and leptine-based insect resistance may be more effective than either resistance alone. High leptine expression has been combined with high *Bt-cry3A* expression in a single potato genotype (Coombs *et al.*, 2002). This line, along with lines that have either *Bt-cry3A* or leptine expression alone, allow researchers to test the effectiveness of combined resistance mechanisms versus individual mechanisms. The primary effort of the potato-breeding project is to combine these two resistance mechanisms into one cultivar. Such breeding efforts have been initiated to develop advanced breeding lines that express leptine-based insect resistance for the chip processing and tablestock industry. These lines have been crossed to advanced breeding lines that have good agronomic performance along with either chip processing or tablestock qualities. The superior individuals from each cross were selected for specific gravity, tuber appearance rating, chip processing, leptine/TGA (total glycoalkaloid) content, and Colorado potato beetle resistance. High performance liquid chromatography (HPLC) procedures are being used to measure leptine/TGA concentration in the potato foliage (Sinden *et al.*, 1986a). The superior selections from this breeding effort will be candidates for combining with the *Bt-cry3A* gene via *Agrobacterium*-mediated transformation (Douches *et al.*, 1998). The same strategy of combining natural and engineered traits can be applied to glandular trichome-mediated resistance. The combination of *Bt-cry3A* gene and glandular trichomes may provide a broader-based

insect resistance providing control of small-bodied insects, such as leafhoppers and aphids, along with the Colorado potato beetle.

Douches and Grafius (2005) provide a recent review of the use of transformation technologies for improving insect resistance in potato, including discussions on management of insect resistance.

Tolerance to abiotic stresses, in addition to biotic stresses, may be a target for enhancement using genetic transformation technologies. Of particular note among abiotic stresses of potato is cold. Potato is grown as a cool-season crop, yet is susceptible to frost damage, resulting in yield losses or complete crop failure. Frost is a major limiting factor in potato production in certain parts of the world (Sukumaran and Weiser, 1972; Chen and Li, 1980; Chen *et al.*, 1999), leading potato breeders worldwide to target improved cold tolerance, in addition to other important traits, in selection criteria. The cold tolerance phenotype is actually the culmination of two distinct traits, nonacclimated freezing capacity and acclimation capacity, which are under differential genetic control (Stone *et al.*, 1993). Wild potato species may be good sources of frost tolerance for improvement of cultivated potato (Hijmans *et al.*, 2003). The D. Carputo laboratory at the University of Naples has extensively used *Solanum commersonii* as a source of frost tolerance (Carputo *et al.*, 2000; Carputo *et al.*, 2003). From a complementary DNA (cDNA) library of *S. commersonii*, De Palma *et al.* (2008) identified cDNAs encoding various desaturases. The *Delta-9* desaturase gene was overexpressed in *S. tuberosum* and resulted in an increased tolerance upon cold acclimation of about 2 °C. Additional genes responsible for frost tolerance in wild species are likely targets of eventual mapping and cloning efforts.

2.1.2 Transgenes for improvement of quality traits

Agriculturally significant quality traits of potato include the level of starch and sugars in the tuber. Of particular note, the accumulation of the hexose reducing sugars glucose and fructose in the potato tuber is undesirable since subsequent frying at high temperatures can cause darkening through a nonenzymatic Maillard reaction,

leading to commercially unacceptable processed food products. Kumar *et al.* (2004) reviewed factors that can affect sugar concentration in the potato tuber, including genetic background and environmental factors in the field and in storage. Storage of potato at cold temperatures reduces tuber loss due to disease and extends storage life by suppressing sprouting. Unfortunately, when stored below 10 °C, the potato tuber converts starch to sucrose and sucrose to glucose and fructose (Coffin *et al.*, 1987; Scheffler *et al.*, 1992), a phenomenon known as “cold sweetening”. Cold sweetening requires additional poststorage, preprocessing tuber treatment, adding expense. Sowokinos (2001) reviewed the benefits of a potato cultivar that can be processed directly from cold storage without additional conditioning, including reduced disease and reduced expense associated with chemical sprout inhibitors and heating potato storage facilities in cold climates. In an attempt to reduce cold sweetening in potato tubers, researchers have applied transgenic approaches to disrupt both the conversion of starch to sucrose and the conversion of sucrose to glucose and fructose.

Uridine-5'-diphosphoglucose pyrophosphorylase (UGPase) catalyzes a rate-limiting step in the conversion of starch to sucrose (Sowokinos, 2001; Kumar *et al.*, 2004). Sowokinos *et al.* (2004) demonstrated sequence polymorphism in UGPases from a collection of six potato cultivars differing in sensitivity to cold sweetening. The authors concluded that UGPase activity might be tightly regulated in the plant in response to varying environmental conditions. Consistently, several researchers have targeted disruption of UGPase activity using transgenic approaches in an attempt to minimize the cold sweetening.

Zrenner *et al.* (1993) examined UGPase transcript levels in different potato plant tissues throughout development and in mature tubers stored at varying temperatures, demonstrating that transcription is highest during tuber expansion and in mature tubers stored for 2 weeks or more at 4 °C. Next, the authors used antisense RNA to disrupt UGPase activity. The coding region of UGPase was isolated from potato cDNA via PCR using primers generated from a previously reported potato UGPase gene. The PCR product was ligated to the CaMV 35S promoter and the octopine-synthase gene polyadenylation signal and the entire construct cloned into vector

pBin19. Digestion patterns were used to identify a plasmid containing the UGPase coding region cloned in an antisense direction. Tubers from plants transformed with the construct showed significant reduction in UGPase transcript levels. Semi-quantitative Western analysis confirmed that UGPase protein had been reduced to as low as 2–5% of that of nontransformed control tubers, correlating well with observed UGPase activity. Importantly, the authors noted no significant difference between transformed and control tubers in total yield, total carbohydrate, sucrose:starch ratio, or hexose sugars. Zrenner *et al.* (1993) concluded that 4% of wild type UGPase activity was sufficient for accumulation of normal levels of carbohydrate in the potato tuber. Although the authors did not specifically look at the phenomenon of cold sweetening, their results may suggest that modifying UGPase activity will not lead to decreased sensitivity to cold sweetening.

Spychalla *et al.* (1994) also used an antisense RNA approach to disrupt UGPase activity in the potato tuber and specifically looked at the effect of UGPase disruption on cold sweetening. The authors identified a potato UGPase clone from a λ gt11 cDNA expression library by probing with polyclonal anti-UGPase sera. A construct consisting of the patatin promoter, the 5' most 0.5 kb of the UGPase cDNA in antisense orientation, and the polyadenylation signal from the nopaline synthase gene was cloned into binary vector pBIN440. Tubers carrying the construct had significantly lower levels of UGPase activity at harvest and throughout 6 weeks of storage at 4 °C. In the most extreme case, UGPase activity in one transgenic line was reduced to 30% that of nontransformed controls. Consistent with the conclusions of Zrenner *et al.* (1993), Spychalla *et al.* (1994) found that partial disruption of UGPase activity did not alter hexose sugar concentrations in the tuber during 6 weeks of storage. However, in contrast to Zrenner *et al.* (1993), Spychalla *et al.* (1994) did note a significant reduction in tuber sucrose in weeks three through six that weakly correlated with UGPase activity. The authors argued that UGPase may play an important role in cold sweetening, especially during long periods (greater than 3 months) of tuber storage (Spychalla *et al.*, 1994).

Borovkov *et al.* (1996) used two RNA silencing approaches to disrupt UGPase: transformation of

potato with a UGPase ribozyme and antisense expression of UGPase. The authors took advantage of a GUC trinucleotide naturally occurring in the UGPase transcript to develop a hammerhead ribozyme (Haseloff and Gerlach, 1988) that would catalyze specific cleavage of UGPase RNA. The ribozyme consisted of the hammerhead catalytic domain flanked by UGPase-derived sequence. The ribozyme was cloned between a CaMV 35S promoter and a functional β -glucuronidase gene (*gus*) followed by the nopaline synthase polyadenylation signal in the binary pBI121 plasmid. The authors also created an antisense UGPase construct consisting of a 1.2 kb genomic fragment from a cloned UGPase gene (containing approximately one-third of the coding region of the gene) cloned in antisense orientation between the CaMV 35S promoter and the functional *gus* gene in pBI121. In total, the authors examined 103 plants transformed with either the ribozyme or the antisense construct. Only 13 plants showed significantly reduced UGPase activity, relative to untransformed controls. In the most extreme cases, UGPase activity was reduced to 50–60% that of control plants. Using field-grown tubers stored for 2 months at 6 °C, the authors identified two transformed lines with significantly lower sucrose accumulation, relative to controls. The authors argued that their results indicate that UGPase plays a critical role in the regulation of carbohydrates in the tuber during storage and predicted manipulation of UGPase levels in the tuber can lead to improved tuber quality (Borovkov *et al.*, 1996).

In plants, enzymes known as invertases play a crucial role in regulating carbon metabolism throughout plant development. Tymowska-Lalanne and Kreis (1998) provide extensive review of the cellular roles of invertases. In potato, invertases are involved in cold sweetening, specifically catalyzing the conversion of sucrose into glucose and fructose. McKenzie *et al.* (2005) examined invertase and UGPase activities in a collection of 15 potato clones with differing sensitivities to cold sweetening. The authors concluded that, for that specific collection of materials, invertase activity was a stronger determinant of cold sweetening sensitivity than was UGPase activity, with stronger invertase activity correlating with increased sensitivity to cold sweetening. Li *et al.* (2006) demonstrated

through an association mapping approach that potato *Invap-b* loci *invGE* and *invGF* play an important role in determining tuber starch and sugar content. These and other findings have led researchers to hypothesize that disruption of invertase activity in the tuber may result in reduced accumulation of glucose and fructose.

Zrenner *et al.* (1996) disrupted invertase activity using an antisense RNA approach. Using a collection of 24 potato genotypes differing in sensitivity to cold sweetening, the authors demonstrated correlation between the amount of hexose sugars in stored tubers and the amount of soluble acid invertases. Next, the authors isolated a potato extracellular acid invertase cDNA by screening a potato library with a homologous probe from carrot. The potato cDNA was cloned in reverse orientation into binary vector BinAR between the CaMV 35S promoter and the octopine-synthase polyadenylation signal. Potato plants transformed with the construct produced tubers showing 12–58% reduction in acid invertases relative to untransformed controls. While transgenic and control tubers stored for 20 weeks at 4 °C had similar levels of total sugars, tubers of transgenic plants displayed reduced hexose and increased sucrose concentrations. The authors concluded that acid invertases are major determiners of hexose:sucrose ratios in cold stored tubers.

Greiner *et al.* (1998) disrupted invertase activity using a different approach. The authors isolated an inhibitor of invertase from tobacco by first purifying and partially sequencing the functional protein, Nt-inh1, and then isolating the corresponding cDNA using reverse transcription (RT)-PCR. Next, the authors transformed potato with a homolog of *Nt-inh1*, *Nt-inhh*, under the control of the CaMV 35S promoter (Greiner *et al.*, 1999). For transformation, the authors used the binary vector BinAR. Transformed plants developed tubers that appeared phenotypically normal and the authors noted no adverse effect on tuber weight or overall yield. Significantly, after 6 weeks of cold storage, the tubers of transformed plants had reduced glucose (up to 83% reduction relative to wild type) and fructose (up to 73% reduction relative to wild type) and increased sucrose (up to 323% increase relative to wild type). The reduction of glucose and fructose in the transgenic tubers was associated with improved processing quality (Greiner *et al.*, 1998).

Sowokinos (2001) indicated that functional redundancy in carbohydrate metabolic pathways of potato can complicate transgenic attempts to modify tuber starch:hexose ratios. Nevertheless, continued characterization of the role of specific invertases in cold sweetening, the isolation of inhibitors of invertase activity, and the transformation of agriculturally important potato cultivars to inhibit cold sweetening seem to be likely future research directions.

2.1.3 Transgenes for modification of industrial characteristics

Transgenic approaches have also been used to modify tuber starch composition for industrial applications. Tuber starch is comprised largely of amylose, a linear $\alpha(1,4)$ -D-glucan polymer, and amylopectin, an $\alpha(1,4)$ -linked, $\alpha(1,6)$ -branched D-glucan polymer. The ratio of linear amylose to branched amylopectin is an important factor for industrial applications and transgenic approaches have been used to alter this ratio. Both amylose-free and amylose-rich potatoes have resulted.

Granule-bound starch synthase (GBSS) catalyzes the synthesis of amylose from ADP-glucose. Visser *et al.* (1991) demonstrated that an antisense approach targeting *GBSS* reduces or even eliminates amylose production in the tuber. In that study, the authors transformed diploid ($2n = 2x = 24$) potato lines with a construct consisting of a full-length potato *GBSS* cDNA in antisense orientation between a CaMV 35S promoter and the nopaline synthase terminator. The construct was cloned into the binary vector pROK-1, which carries the *NPTII* gene for resistance to kanamycin, and was transferred to potato via *Agrobacterium rhizogenes*. Using a rapid iodine staining procedure, the authors demonstrated that the construct disrupted amylose accumulation in most roots but that the effect was reversible and unstable. Next, the authors regenerated 16 clones, from which they produced tubers. Despite the results from the analysis of roots, 11 of the 16 clones produced tubers that were amylose free, 2 of the 16 clones produced tubers composed of a mixture of cells, some being amylose free and some being amylose rich, and three of the 16 clones produced tubers that were amylose rich. Tubers from all clones, regardless of starch

composition, displayed reduced GBSS activity, relative to the untransformed controls. Inhibition ranged from 70% to 100%. Subsequently, Kuipers *et al.* (1994) generated tetraploid antisense-GBSS potato lines. The authors used two different constructs, including the construct used by Visser *et al.* (1991), described above, and a similar construct in which the full length *GBSS* gene, in antisense orientation, was under the control of the native *GBSS* promoter, rather than the CaMV 35S promoter. The latter construct was cloned into vector pPGB-1, which is derived from pBI121 and includes the *NPTII* gene for kanamycin resistance. Of 66 transgenic clones analyzed, 10 bore tubers displaying no GBSS activity and no amylose accumulation. A general correlation between transgene copy numbers and degree of *GBSS* silencing was noted and the authors concluded that a minimum of two transgene copy numbers was needed to completely silence *GBSS*. As might be expected, the authors also noted a correlation between the amount of accumulated *GBSS* transcript and accumulation of amylose. Taken together, these studies demonstrate that antisense technology can be successfully utilized to alter potato tuber starch composition.

While the efforts described above were aimed at the creation of amylose-free tubers, other researchers have used transgenic approaches to create amylose-rich tubers. Schwall *et al.* (2000) achieved high amylose production by simultaneously suppressing two genes, *starch branching enzyme A* (*SBE A*) and *starch branching enzyme B* (*SBE B*). These genes encode proteins involved in the synthesis of branched amylopectin. Gene silencing was achieved by two separate rounds of transformation. First, a potato line was transformed with an *SBE B* construct consisting of a 2.3 kb partial cDNA fragment of the potato *SBE B* gene in antisense orientation between double CaMV 35S promoters and the CaMV 35S polyadenylation signal. This construct, cloned into binary vector pBIN19, was delivered via *A. tumefaciens* (Safford *et al.*, 1998). Four transformed lines showing low levels of *SBE B* activity were subsequently retransformed with the antisense *SBE A* construct of Jobling *et al.* (1999). This construct consisted of a 1.2 kb partial cDNA fragment of the potato *SBE A* gene in antisense orientation between two CaMV 35S promoters and the nopaline synthase terminator.

The construct was cloned into vector pGPTV-HYG, which encodes resistance to hygromycin B, and delivered via *A. tumefaciens*. The authors surveyed three independent double transformation lines and demonstrated that SBE A and SBE B activity had been reduced to nearly undetectable levels. Nineteen of 71 double transformed lines surveyed had $\geq 40\%$ amylose content, with the best having amylose content of 75–89%. Significantly, double transformed lines had an altered starch structure and some lines completely lacked wild type amylopectin. Potato starch from transformed lines also showed up to sixfold increases in phosphorous content. The authors concluded that the high-amylose, low-amylopectin, high-phosphorous potato starch generated through transformation technology offered novel industrial and food utilities (Schwall *et al.*, 2000).

2.2 Transformation Methods

Efficient methods for *A. tumefaciens*-mediated transformation of potato leaf, stem, tuber, and microtuber tissues were developed long ago (see for example Shahin and Simpson, 1986; De Block, 1988; Sheerman and Bevan, 1988; Tavazza *et al.*, 1988; Ishida *et al.*, 1989; Szychalla and Bevan, 1991; Visser, 1991; Kumar, 1995). As reflected in Table 3, *Agrobacterium*-mediated transformation has been widely employed. Alternative approaches, including polyethylene glycol (PEG)-mediated transformation of protoplasts (Feher *et al.*, 1991; Craig *et al.*, 2005) and microprojectile bombardment or biolistics (Romano *et al.*, 2001; Romano *et al.*, 2003; Craig *et al.*, 2005; Romano *et al.*, 2005) have been reported for potato. Ercolano *et al.* (2004) demonstrated successful biolistic transformation of potato with a 106 kb BAC fragment and advocated for the approach as a means of speeding positional cloning efforts. However, to date, PEG-mediated and biolistic methods for transformation of potato have been of limited application. Protocols for the transformation of the potato plastid genome have also been reported (Sidorov *et al.*, 1999; Nguyen *et al.*, 2005).

2.3 Selection of Transformed Tissue

Antibiotic resistance, and especially resistance to kanamycin, has been the primary means of

selecting transformed potato tissues (Table 3). Selection of transgenic potato based on resistance to herbicide has been reported (Andersson *et al.*, 2003) but has not been widely employed. Transformation methods yielding transformed plants lacking a selectable marker have also been developed. de Vetten *et al.* (2003) used a PCR-based screen of regenerants to identify transformed potato genotypes lacking both a selectable marker gene and vector backbone DNA. Wang *et al.* (2005) developed a binary vector utilizing the Cre/lox system. The authors demonstrated the successful simultaneous heat shock-mediated elimination of both Cre and antibiotic resistance genes from transgenic tobacco and speculated that the system could be adapted for potato. Rommens *et al.* (2004) replaced the *A. tumefaciens* transfer DNA with sequences derived from the potato genome. Paired with different strategies for marker-free selection or selectable marker eradication, the approach yielded up to 29% of regenerants carrying the transgene and lacking a selectable marker. Transformation strategies that do not require the stable integration of selectable marker genes may become increasingly important in addressing consumer and processor concerns associated with genetically modified potatoes.

2.4 Regeneration of Whole Plant

Potato, like several other species in the Solanaceae, is fairly responsive to *in vitro* manipulation, including regeneration of whole plants from callus tissues. Multiple successful regeneration protocols (see for example, Shahin and Simpson, 1986; Edwards *et al.*, 1991; Visser *et al.*, 1991; Cearley and Bolyard, 1997) and numerous modifications have been reported. However, potato cultivars differ substantially in response to regeneration efforts. Heeres *et al.* (2002) attempted *Agrobacterium*-mediated transformation of 16 different potato cultivars using two different transformation protocols that differed in regeneration conditions. Considerable genotype-to-genotype variation was noted, with regeneration efficiency ranging from 0.3% to 55.7%. The authors speculated based on known pedigrees of the genotypes studied that regeneration efficiency may be under the control of specific genetic factors. Consistent with the results of Heeres *et al.* (2002),

transformation protocols optimized for specific potato cultivars have been reported (Cearley and Bolyard, 1997; Gustafson *et al.*, 2006).

2.5 Testing of Transgenic Lines

The transformation and regeneration process can sometimes have unintended effects on plant phenotypes. Phenotypic changes may result from pleiotropic effects of the transgene or from somaclonal disruption of normal genome organization or function (Kumar, 1994). Variation in expression of the transtrait is also common. Consequently, testing of transgenic potato clones has focused simultaneously on successful expression of the transtrait and recovery of an otherwise characteristic cultivar phenotype. Commercially, potato is clonally propagated, so sexual transmission of the transgene may not be of primary concern. However, clonal generation-to-clonal generation variation in transgene effect can occur, necessitating testing across several generations.

Heeres *et al.* (2002) noted visible morphological deviation of transgenic plants from the untransformed controls for 10.3% of regenerants in greenhouse tests and 19.6% of regenerants in field tests. Deviations included changes in tuber appearance and leaf color and shape. Interestingly, the authors noted that independent regenerants that deviated from wild type did so in a cultivar-specific fashion. Thus, for example, deviations for regenerants of cultivar Indira tended to have an irregular leaf surface and characteristic discolorations (Heeres *et al.*, 2002). Transformation and regeneration may also affect traits of agronomic significance. Schwall *et al.* (2000) reported that disruption of the potato *SBE B* gene reduced overall yield relative to untransformed controls and that high amylose potato lines, achieved through simultaneous silencing of *SBE A* and *SBE B* yielded elongated tubers, relative to controls. Kuipers *et al.* (1992) examined four diploid amylose-free potato clones generated through antisense disruption of *GBSS*, comparing yield with that of untransformed control. The authors demonstrated that each of the four lines produced fewer tubers than the control, but that total yield of two of the lines was statistically identical to that of the control

and two of the transformed lines produced tubers that were significantly heavier than those of the control. The authors concluded that there is significant potential for modification of traits of potato through transgenic methods without sacrificing yield. Similarly, Heeres *et al.* (2002) examined yield in several independent lines of two tetraploid amylose-free transgenic potato cultivars. The authors note that the average yield of one cultivar was 95% of that of the untransformed control and that one transformed line of the second cultivar actually yielded 5% more than the corresponding untransformed control. Taken together, these studies demonstrate that, while the transformation and regeneration processes may induce genetic changes and alter agronomic traits, transformants that are substantially similar to wild type (with the exception of the transtrait) can be readily identified in many cases.

Large-scale deployment of transgenic plants warrants special attention to transgene function under varying environmental conditions and in different genetic backgrounds. As a case study, consider current efforts to deploy the late blight resistance gene *RB*. Toward devising a strategy for successful gene deployment, researchers have combined field- and greenhouse-based and laboratory-based assays.

Field and greenhouse assays have demonstrated the broad-spectrum nature of *RB* and have tested effects of transformation on plant fitness. The map-based cloning of *RB* was initiated by generating interspecific somatic hybrids between the wild *S. bulbocastanum* and cultivated potato (Helgeson *et al.*, 1998). Analysis of late blight resistance in the somatic hybrids and backcrosses to potato in greenhouse tests and in field trials in Wisconsin, USA, demonstrated that *RB* imparts resistance to *P. infestans* race US8, the predominant pathotype in the United States today (Helgeson *et al.*, 1998). Subsequent testing of backcross materials in the Toluca Valley of Mexico, an area of the world with ideal late blight epidemic conditions and an extremely diverse, sexually mating pathogen population, revealed that *RB* also imparts broad-spectrum, pathogen race nonspecific resistance (Naess *et al.*, 2000). Fine molecular mapping and eventual gene cloning ensued (Naess *et al.*, 2000; Bradeen *et al.*, 2003; Song *et al.*, 2003b), enabling the *RB* transgene to be tested in a variety of cultivated

potato genetic backgrounds and in a variety of different locations. Since its cloning, *RB* has been transformed into several important potato cultivars (e.g., ‘Russet Burbank’, ‘Superior’, ‘Dark Red Norland’) and has been tested in replicated greenhouse trials at the University of Wisconsin, USA, and the University of Minnesota, USA, and in replicated field trials in the US states of Minnesota, Michigan, and Oregon. Field trials have also been conducted in Europe and India. Genetic background-dependent variation in *RB* function has been noted (Bradeen, unpublished) but in every trial, the intact transgene has imparted the rate-limiting, broad-spectrum resistance reported by Song *et al.* (2003b) (Figure 2). In greenhouse tests, Halterman *et al.* (2008) examined the effects of varying *P. infestans* inoculum concentration on disease development in transgenic potato. Using two different *P. infestans*

isolates at concentrations ranging from 258 300 to 391 665 sporangia per plant, the authors demonstrated no significant difference in disease scores. In field plots, the same authors demonstrated for four different potato cultivars that addition of the *RB* transgene does not alter plant fitness, as measured by tuber yield (Halterman *et al.*, 2008).

Laboratory-based characterization of *RB* has also been helpful in determining how best to utilize this gene in a production setting. Significant contributions have included the development of PCR markers for marker-aided selection and transgene expression. Colton *et al.* (2006) developed PCR markers for selection of somatic hybrid-derived breeding lines. The authors demonstrate that *RB* markers can be used to accurately predict late blight resistance. It is expected that the approach will be useful

Figure 2 Transgene *RB* imparts resistance to foliar late blight. A photograph of a late blight screening nursery at the University of Minnesota. Potato cv. Katahdin, a normally late blight susceptible cultivar, was transformed with the *RB* late blight resistance gene from the wild potato *Solanum bulbocastanum* (Song *et al.*, 2003b). Rows of transgenic materials (green plants) were planted between rows of the late blight susceptible potato cv. Norchip (dead, brown plants). Approximately 60 days after planting, the field was inoculated with *Phytophthora infestans* race US8. Frequent overhead irrigation kept humidity levels high, favoring disease development. Photograph was taken 21 days after inoculation. While untransformed potato was killed by disease, the *RB* transgenic lines remain uninfected [Reproduced from Millett and Bradeen (2007). © Springer]

to breeding programs aimed at accessing late blight resistance using somatic hybrid, instead of transgenic methods. Millett and Bradeen (2007) developed complementary PCR and RT-PCR assays that are specific for the *RB* transgene. Their approach took advantage of single nucleotide polymorphisms that were introduced into the transgene as an artifact of cloning (Song *et al.*, 2003b). Using mismatch amplification mutation assay (MAMA)-PCR (Cha *et al.*, 1992), the authors developed primers that are so specific for the *RB* transgene that they can differentiate the transgene from the *S. bulbocastanum* endogenous gene from which it was cloned (Millett and Bradeen, 2007). The method has been recently adapted for real time quantification (Bradeen, unpublished). The J. Bradeen laboratory at the University of Minnesota, USA, is now using the assay to examine the expression of transgene *RB* in different genetic backgrounds, at different stages in plant development, in different plant tissues, and under different environmental conditions (Figure 3). Paired with phenotypic tests for disease resistance, this research promises to provide guidelines on how best to integrate transgene *RB* into disease management practices.

Other research is aimed at understanding the evolution of *RB* and the isolation of novel, functional *RB* alleles. Song *et al.* (2003b) demonstrated that LR-PCR can be used to isolate full-length, intact resistance gene copies. *RB*, like many other plant resistance genes, exists in the genome as one functional copy within a larger cluster of related copies (paralogs) of differential function. The *RB* locus is 79.6–85.6% similar to its paralogs at the DNA sequence level (Song *et al.*, 2003b). Sanchez and Bradeen (2006), aiming to use LR-PCR to isolate *RB* alleles from a broad survey of *S. bulbocastanum* genotypes, optimized LR-PCR, specifically seeking reaction conditions and appropriate primers that could distinguish between *RB* alleles and paralogs. Subsequently, the authors demonstrated the utility of the approach by isolating *RB* alleles from 17 different *S. bulbocastanum* genotypes (Sanchez, 2005). DNA sequence analysis revealed broad distribution of *RB* alleles within the species, implying extensive gene flow. The authors also isolated a novel *RB* allele that putatively arose through an interlocus, *in planta* recombination event (Sanchez, 2005). Functional tests of the newly recovered allele are ongoing. The isolation of additional functional *RB*

Figure 3 Exploring how environment affects transgene *RB*. (a) A photograph demonstrating the effects temperature has on plant morphology. Shown are three plants of the transgenic line SP2577 (cv. Dark Red Norland + the *RB* transgene) at 64 days after planting from greenhouse-produced tubers. The plants were grown in growth chambers at constant temperatures; left: 10°C, middle: 20°C, right: 30°C. Temperature substantially altered plant morphology and growth rates. Note stunted morphology of the 10°C plant and leggy appearance of the 30°C plant. The plant grown at 20°C is postflowering; plants grown at other temperatures have not yet flowered. (b) A photograph of an agarose gel showing results of RT-PCRs using an assay specific for the *RB* transgene (Millett and Bradeen, 2007). Lanes are (left to right): DNA size standard; six RT-PCRs using RNA extracted from transformed line SP2577 (+) or cv. Dark Red Norland (-; untransformed control) grown at 10°C, 20°C, or 30°C, as labeled; S: RT-PCR using RNA extracted from cv. Superior (independent untransformed control); K+: RT-PCR using RNA extracted from cv. Katahdin transformed with *RB* (independent positive control); and W: RT-PCR using water (no RNA) as a template (negative control). Upper fragment, present in all lanes except water, is an amplicon from the *RNA Polymerase II* gene and serves as an internal positive control for each reaction. The second fragment, indicated with an arrow, is an amplicon specific for the *RB* transgene. Note that the fragment is present in the positive control lane (K+) and absent in the negative control lane (S). The fragment is detected in transformed line SP2577 at 10°C, 20°C, and 30°C but is absent in the untransformed cv. Dark Red Norland at all temperatures. The lower fragment, present in all lanes except water, results from amplification of sequence not associated with *RB* and serves as an additional internal control [Reproduced from Millett and Bradeen (2007). © Springer]

alleles may allow improved transgene durability through allele pyramiding.

Consistent with research predicting *RB* to be of broad utility for the protection of potato against the late blight pathogen, there is current commercial interest from US and European companies in developing and releasing late blight resistance potatoes carrying the *RB* transgene.

2.6 Regulatory Measures for Field Release of Transgenic Potato

Regulatory measures related to the environmental testing, transport, commercial or industrial use of transgenic potato have been developed to ameliorate potential risks to the environment and the consumer. Risk evaluation factors may include the origin of the transgene, the components of the construct, including the promoter and terminator sequences, the presence of selectable markers, the potential for the transgene to escape including the crossability of potato with wild species indigenous to an area and the likelihood of transgenic potato survival from one season to the next, and likely health risks associated with the production of the transprotein. In some cases, laboratory or clinical tests demonstrating the health effects of the transgene may be warranted. Studies demonstrating that transformation of potato with specific transgenes resulted in less variation in the tuber proteome (Lehesranta *et al.*, 2005) and metabolome (Catchpole *et al.*, 2005) than has been achieved through conventional breeding may have effects on current regulations. Regulations and regulatory agencies are developed by individual nations although some transnational agreements have also been established. Here the regulation in the United States of transgenic crops, with emphasis on potato, is discussed as an illustration of the complex nature of this field.

The field release of transgenic potato either for research purposes or for commercial production may involve regulations established by three different US agencies: USDA Animal and Plant Health Inspection Service (APHIS), the Environmental Protection Agency (EPA), and the Food and Drug Administration (FDA). The three agencies jointly maintain the “U.S. Regulatory Agencies Unified Biotechnology Website” (<http://usbiotechreg.nbii.gov>), a useful portal for those interested in up-to-date US regulations on

transgenic food crops. APHIS, EPA, and FDA differ in terms of the scope of their missions and each agency has established rules and guidelines for the safe release of transgenic crops. Although guidelines continue to evolve, all agencies provide substantial advice on safe handling and testing procedures.

APHIS is charged with protecting agriculture from diseases and pests. The agency regulates the field release of transgenic crops in order to minimize unintentional negative effects on the environment or agriculture. APHIS has established both a “notification” and a “permit” process for the interstate transport and field release of transgenic plants for experimental purposes. Currently, qualification for the notification process requires that the transgene originates from an organism other than a human or animal pathogen, the functions of the transgene construct and product are known, the transgene product does not have adverse human, animal, or plant health effects, the transgene product is not a virus particle, the transgene does not result in a product intended for industrial or pharmaceutical use, and the transgene is stably integrated into the plant genome. The APHIS notification process is less stringent than the permits application process, which requires more detailed scientific evaluation. Applications requiring an APHIS permit include testing of transgenic potatoes producing pharmaceutical products and value-added components intended for human consumption. In either case, APHIS has established a series of compliance guidelines. For potato, these include isolation of transgenic plots from nontransgenic potato by at least 0.25 mile (0.4 km) or establishment of a pollen trap crop consisting of at least 30 ft. (9.14 m) of nontransgenic potato planted on all sides of the transgenic crop. Field monitoring and destruction of volunteer plants in the year following a transgenic potato field test are also required. APHIS specifies the timing and content of reports detailing the results of field trials. On-site assessments by USDA and/or state regulatory agencies may be conducted.

Among other activities, the EPA regulates the use of pesticides to minimize environmental and human health effects. In this capacity, EPA also regulates products produced by transgenic plants that protect against insects and pathogens. While the EPA specifically regulates these pesticidal compounds produced by transgenic plants, termed

“Plant Incorporated Protectants” (PIPs), it does not regulate the transgenic plant *per se*. EPA approval of a PIP requires evaluation of risk factors including unintentional effects on human health, nontarget organisms and the environment, the likelihood of transgene escape, and the need of a pest resistance management plan. EPA issues both PIP registrations and PIP experimental use permits. Registration of a PIP is required before the product can be marketed. The registration process entails careful review by EPA of the pesticidal component(s), the crop and location where it is to be used, frequency, amount, and timing of use, and disposal practices, as warranted. Like other pesticides, PIPs are evaluated in terms of human health and environmental risks. Registration of a PIP may take as little as 1 year or up to several years. Once registered, a PIP can be safely used for crop protection, provided registration label guidelines are followed. A PIP experimental use permit is required if the PIP in question is not registered or if a nonregistered application of a PIP is to be tested on more than 10 acres (4.05 ha) of land.

The FDA is charged with maintaining food safety and accurate labeling and has established guidelines for the regulation of transgenic crops intended for human consumption. These guidelines were first adopted in 1992. An individual or company interested in releasing a transgenic crop for commercial production must notify the FDA of intention to do so. Discussions on the food safety of the product ensue and generally require that the person or company intending to release the transgenic product demonstrate its safety through relevant research. This research may focus on the source of the transgene, comparison of transformed and nontransformed food products in terms of known allergens, toxins, and antinutrients, and simulated digestive tests of the transmodified protein. Occasionally, controlled animal or serum testing is also required. The FDA recognizes that no food product, whether transgenic or not, is completely risk free in terms of allergens, toxins, and antinutrients. Accordingly, transgenic food products that do not differ substantially from their traditionally bred counterparts in terms of these components are generally regarded as safe. In addition to mandated regulations, those developing transgenic foods may apply additional safety standards. For

example, companies may opt to not use transgenes from plants known to harbor allergens. In a US General Accounting Office conducted survey of scientists from the FDA, US academic and research institutions, biotechnology companies, and the EU, scientists agreed that current testing standards were adequate to ensure the comparable safety of transgenic foods (GAO, 2002). The same report, however, also points out that more sophisticated applications of transformation technology in the future (e.g., compositional and nutritive modification of crop plants) may require improved or altered testing procedures.

3. FUTURE ROAD MAP

3.1 Expected Products

Future efforts will likely yield commercially important potato cultivars carrying transgenes for improved disease resistance. Late blight, nematodes, and viruses are likely early targets of these efforts. The complete sequencing of the potato genome, an ongoing effort, will provide researchers with bioinformatics tools to speed map-based isolation of genes, including disease resistance genes. The development of improved molecular methods for rapid gene cloning (Sanchez and Bradeen, 2006) may have similar effect. As a result, the number of available resistance transgenes is certain to increase rapidly. Genes from more distantly related plant species may also be more widely utilized to achieve disease resistance in potato. Resistance transgenes against the same pathogen or different pathogens are likely to be pyramided in a common line. These efforts will require continued testing of transgenes in different genetic backgrounds and in different environments. Continued development and optimization of molecular tools to study transgene function and behavior are likely.

Cold sweetening is a costly processing issue. Researchers are likely to continue to elucidate the *in planta* regulation of this phenomenon and devise transgenic strategies for its obviation. As more efficient and reliable RNA silencing technologies emerge, they are likely to be used to target key genes involved in the cold sweetening phenotype, especially UGPases and invertases. RNA silencing technologies are also

likely to continue to be used to manipulate tuber starch composition, with continued research effort focusing on starch synthase and starch branching enzyme genes. More sophisticated refinement of starch composition is likely.

Transgenic technologies will also be used to improve the nutritional quality of potato. Potatoes high in carotenoid, anthocyanin, antioxidant, and vitamin E content may result. Researchers may also use transformation technologies to enhance the already notable levels of vitamin C in the potato tuber. Recent efforts to characterize flavor components in potato may yield an improved understanding of the genetics of flavor, opening the potential for eventual gene isolation and transformation.

Because potato can be easily and cheaply produced in most growing regions of the world, this crop plant holds considerable promise for the *in planta* production of vaccines. Toward this effort, potato has been transformed to synthesize the capsid protein of Norwalk virus (Tacket *et al.*, 1998) and a fusion protein including a HIV-1 envelope glycoprotein (Kim *et al.*, 2004). In a double blind trial, Thanavala *et al.* (2005) demonstrated an increase in blood serum, antihepatitis antibody titer in up to 62.5% of previously vaccinated participants who consumed raw potato tubers from plants transformed to produce hepatitis B antigen. Significantly, this research demonstrates the potential for developing an oral-administered plant-based vaccine that can be produced locally and inexpensively. Research toward development of potato as a factory for vaccines and other pharmaceutical compounds is likely to continue.

Mullins *et al.* (2006) reviews other potential attributes of potato that may be achieved or enhanced through transformation, including the improvement of tuber-derived flour, reduced tendency of tubers to sprout in storage, and the *in planta* production of biodegradable plastics.

3.2 Addressing Risks and Concerns

For transgenic potato, as for most other transgenic crops, assessment of human health risks associated with a transformation event has included careful research to explore the global effects of transgenes on the crop. Of particular note, recent research

has explored the effects of transformation on the potato tuber proteome and metabolome.

Lehesranta *et al.* (2005) reported proteomic comparison of tubers from 32 nontransgenic potato genotypes and from transformed lines originating from three different transformation experiments, along with tubers from relevant controls. On 2-D gels, nine protein spots out of a total of 730 spots differed significantly in intensity between transformed tubers and nontransformed controls. Seven of the differential spots were identified and included defense related proteins, proteins involved in protein destination and storage, and proteins of unknown function. The differences between transformed and untransformed tuber proteomes were insufficient to statistically separate the protein sets. Additionally, variation between transformed tubers and their untransformed counterparts was much lower than that observed between the 32 nontransgenic genotypes (Lehesranta *et al.*, 2005).

Catchpole *et al.* (2005) compared the metabolomes of transgenic potato tubers and their untransformed controls. The researchers used transgenic lines generated in two independent studies. Both groups of lines were engineered to produce high levels of inulin-type fructans, but through the activity of two distinct transgenes. For reference, the researchers also characterized the tuber metabolomes of a small collection of disparate, untransformed potato cultivars. The research utilized a hierarchical strategy for comprehensive metabolome characterization. This strategy was designed to provide (a) a general overview of the tuber metabolome via nonselective metabolite fingerprinting, revealing any gross distinctions between transgenic and nontransgenic metabolomes, (b) a detailed global view of specific metabolites, and (c) a targeted analysis of metabolites differing between transgenic and nontransgenic tubers. Using flow injection electrospray ionization, gas chromatography/ time of flight mass spectrometry, and liquid chromatography mass spectrometry, the researchers identified a total of 15 ions that significantly discriminated transgenic tubers from their nontransgenic controls. Each of these ions was fructans related, consistent with the goal of the original transformation effort. Importantly, the researchers reported that only anticipated metabolites, including those found in the untransformed controls and those conditioned

by the transgenes, were identified in transgenic tubers. Furthermore, variation observed in the metabolomes of untransformed potato cultivars was considerably greater than that observed in the transgenic lines. The researchers concluded that transformation of potato with the transgenes tested did not substantially alter the metabolite composition of the tubers (Catchpole *et al.*, 2005).

Testing for food safety is not a black and white issue. But the “-omics” approaches utilized by Lehesranta *et al.* (2005) and Catchpole *et al.* (2005) are among the first attempts to globally characterize intentional and unintentional changes induced by transformation of a food crop. Interestingly, both studies concluded that the variation inherently present in conventionally bred potato cultivars far exceeds that generated through transformation technologies.

In addition to human health and safety issues, unintentional escape of a transgene into wild relatives of crop plants is an issue of concern when deploying transgenic crops. The cultivated potato is a tetraploid ($2n = 4x = 48$), 4EBN species. The approximately 200 wild potato species comprise primary, secondary, and tertiary gene pools for cultivated potato. These species are distributed from the southwestern United States, throughout Mexico and Central America, into southern South America. In other regions of the world, the risk of transgene escape appears to be minimal owing to the lack of species sexually compatible with cultivated potato (Eijlander and Stiekema, 1994; Love, 1994; McPartlan and Dale, 1994). Where wild potato species do occur, the potential for gene flow between cultivated transgenic potato and wild potato species, and especially the potential for pollen transfer from transgenic potato to the wild species, warrants careful consideration prior to transgene deployment.

The wild potato species exist as a ploidy series from diploid, to tetraploid, to hexaploid. Observed EBNs include 1, 2, and 4. Theoretically, species with 1EBN or 2EBN are sexually incompatible with cultivated potato. However, naturally occurring polyploidization or the production of 2N gametes, both documented events in wild potato species, can circumvent the mismatched EBN-imposed crossing barrier. Jackson and Hanneman (1999) examined the frequency of $2n$ pollen production in wild potato and the crossability

of cultivated and wild potatoes under controlled conditions. In total the authors examined 121 species representing 17 of the 19 potato series. The researchers found $2n$ pollen production in every series and every species examined, noting that frequency of $2n$ pollen varied considerably. In general, genetic distance between cultivated potato and wild potato correlated with crossability. Genetically primitive, 1EBN diploid species from North and Central America could not be crossed with cultivated potato. From 1003 crosses between these species, no seeds were set. Crosses were conducted using the wild species both as the male (831 crosses) and as the female (172 crosses). More advanced 2EBN and 4EBN wild species from these same regions, however, could be crossed with cultivated potato. For example, species belonging to series *Demissa*, including *S. demissum*, the source of the *R1-R11* late blight resistance genes that were long ago introgressed into cultivated potato, produced an average of 0.2 seeds per pollination when used as a male parent and an average of 6.6 seeds per pollination when used as a female parent (Jackson and Hanneman, 1999). Furthermore, crosses between cultivated potato and South American wild potatoes were frequently successful. Genetic distance from cultivated potato dictated whether these wild species were successful as only a male parent or as both a female and a male parent. In general, the more distantly related species functioned successfully only as a male parent. Seeds from successful crosses varied considerably in viability and F_1 sterility was commonly noted (Jackson and Hanneman, 1999). While this study underscores the potential for gene flow between cultivated potato and wild species, it must be interpreted in light of the ideal controlled pollination conditions employed, including the use of a cut-stem pollination method with no parallel in the wild. Clearly, further refined study of the fate of interspecific hybrids and of introgressed chromosome regions in the wild is warranted.

Transgenes may also move from one cropped field to another. To assess the risk of transgene escape, Flannery *et al.* (2005) employed a numerical model incorporating the frequency of sexually compatible wild species in a region, the likelihood the transgenic crop will flower and produce viable pollen, the average distance pollen is likely to travel from the field, the mating system

of the crop plant, and the probability an F_1 hybrid would become established in a region. Applied to Ireland, a region lacking sexually compatible wild species, the researchers concluded the risk for transgene flow from transformed potato was mainly from one cultivated potato to another. While many commercial potato varieties produce low levels of viable pollen and 95% of potato pollen travels 10 m or less from the source, the researchers concluded there is some low-level risk of unintentional transgene flow. This risk is most notable for regions of Ireland engaging in true seed production of potato (Flannery *et al.*, 2005). This research is the first of its kind and serves to provide a baseline assessment for developing effective management practices for transgenic crops, including recommendations on physical isolation of transformed and nontransformed crops.

Mullins *et al.* (2006) detailed the need to integrate effective pest resistance management strategies into transgenic potato production systems. The authors advocated for the use of nontransgenic “refuges” near transgenic crops, providing a low or no selection pressure area where resistance to the transgene imparts no survival benefit. The use of refuges theoretically expands the effective life of a transgene. Mullins *et al.* (2006) also advocated for pyramiding different pest resistance transgenes in a common line. Combining different disease or insect resistance genes is thought to present the pest simultaneously with several different strategies of defense, requiring a pest to perish or overcome the multiple resistances. This too is thought to extend the effective life of a transgene. With the recent cloning of several resistance genes effective against the late blight pathogen (Table 3), it is not surprising that there is current commercial interest in pyramiding late blight resistance genes in a common line (Mullins *et al.*, 2006). As additional genes for resistance against pathogens and insects are cloned, pyramiding efforts, in an attempt to extend transgene functional life, are likely.

3.3 Expected Technologies

Major potato genomics efforts in recent years in Europe, Canada, and the United States are shedding light on the genetic control of many important

potato traits. Ongoing efforts to sequence the entire potato genome will provide researchers with new tools for gene pathway characterization and isolation. To match an anticipated increase in the number of potato transgenes emerging from these and other research efforts, transformation systems for potato are also likely to continue to improve. While *Agrobacterium*-mediated transformation of potato has been widely used (Table 3), the potential to develop alternative systems based on other bacteria (Broothaerts *et al.*, 2005) may provide enhanced transformation efficiencies. Other improvements in transformation technologies for potato will focus on methods for multigene insertions, reduction of transgene variability, and development and optimization of selectable marker-free approaches.

As more is learned about the control of complex traits in potato, there is an emerging need for efficient transformation approaches for the simultaneous insertion of multiple transgenes, enabling, for example, insertion of entire metabolic pathways or QTLs. Toward this goal, Chen *et al.* (2006) developed an *Agrobacterium* vector allowing simultaneous transformation with multiple genes. In a proof-of-concept experiment, the authors demonstrated transformation of tobacco with seven target DNA sequences. This and similar vectors with multigene capabilities may be essential for the routine polygenic transformation of potato. Other researchers are using biolistic approaches to insert large fragment DNAs into potato (Ercolano *et al.*, 2004). This practice may be increasingly utilized both for multigene insertions and to speed map-based cloning efforts.

Variation in the expression and function of transgenes currently necessitates the screening of a large number of transformants to identify lines of maximal effect. Butaye *et al.* (2005) reviewed causes in variation in transgene expression that are observed from one transformation event to the next. These include variation in transgene copy number, site of insertion, and RNA silencing. Variation in the number of transgenes inserted has been widely reported. When multiple copies of a transgene are inserted, the frequency of gene silencing or even loss of the transgene through chromosomal rearrangements increases, leading to gross variation from transformant to transformant in trait expression. For this reason,

researchers are exploring methods of assuring single copy insertions. Srivastava *et al.* (1999) utilized the Cre/*lox* system to achieve single insertion transgenic wheat. The researchers developed a construct in which the transgene was sandwiched between inverted *lox* sites. In wheat, as in many plants, the simultaneous insertion of multiple, tandem transgenes is commonplace. Srivastava *et al.* (1999) demonstrated that transformed wheat lines carried several copies of their construct and, presumably, some of these existed as a tandem array. In the presence of Cre recombinase, direct *lox* sites recombine, eliminating intervening DNA from the genome. The researchers reasoned that if two or more transgenes and their bordering inverted *lox* sites were arrayed in tandem, recombination between direct orientation *lox* sites from adjacent constructs would result in elimination of all but one copy of the transgene. Accordingly, the researchers crossed Cre into the genome of the multicopy transformed wheat lines, demonstrating that the enzyme did indeed catalyze resolution of arrayed multitransgenes into a single copy. Whether or not the Cre/*lox* system will become an important tool for manipulating transgene copy number in the potato genome remains to be seen.

Related to transgene copy number is RNA silencing through endogenous processes that are thought to have evolved to target mutant or “foreign” RNA molecules. Much has been learned about RNA silencing in plants and other organisms in recent years (reviewed in Tijsterman *et al.*, 2002; Matzke and Birchler, 2005). Current understanding of the RNA silencing phenomenon predicts that tight regulation of transgene copy numbers may reduce the occurrence of the phenomenon. Thus, utilizing the Cre/*lox* system or other approaches of manipulating transgene copy numbers may ameliorate the effects of RNA silencing.

The Cre/*lox* system has also been used to achieve quasi site-specific transgene insertions (reviewed in Ow, 2002). Other systems for site-directed transgene insertion in plants have been reported (reviewed in Butaye *et al.*, 2005), but efficiencies remain very low. The development of efficient site-directed insertion technologies appears to have significant potential for improving potato transformation technologies and is likely to remain an active research pursuit.

The development of selectable marker-free transgenic potato may be an important approach to addressing consumer concerns with current transformation technologies (detailed below) and is an area of current research emphasis. The use of PCR-based screening (de Vetten *et al.*, 2003), the Cre/*lox* system (Wang *et al.*, 2005), or other technologies to identify or generate potato transformants lacking selectable marker genes is likely to continue. Also likely to continue is the development of transformation vectors derived from plant sequences (Rommens *et al.*, 2004).

3.4 Public and Industrial Perceptions of Transgenic Potato

In the United States, processor resistance to genetically modified potato represents a social barrier that may limit commercialization of transgenic potato in the near future. In Europe, Japan, and other parts of the world, public opinion against genetically modified foods in general is likely to continue to have a similar effect. Education efforts aimed to achieve public awareness of the origin of transgenes and both the benefits and drawbacks of transformation technologies continue to be important.

Recognizing that the source of a transgene can have significant impact on how the gene is regulated by governments and perceived by consumers, researchers have begun to adopt naming conventions and classification schemes that reflect the relatedness of donor and recipient species. Nielsen (2003) proposed such a system, advocating for five categories of relatedness between donor and recipient based on species classification. These same categories are ranked in terms of the potential for the target gene to be transferred or arise through conventional breeding technologies. For example, the “intragenic” category would encompass instances in which a gene is moved within a single genome or within a species. Genetic distance between donor and recipient in this case would be low and the target gene could be accessed through conventional breeding. At the other extreme, the “xenogenic” category would encompass instances in which the target gene is designed by researchers in a laboratory. Genetic distance between the donor and the recipient would be ranked as high and the target gene could

not be accessed through conventional breeding. The categories proposed by Nielsen (2003) are intended to provide a framework to discuss transgenic technologies for risk assessment at the scientific, regulatory, and ethical levels.

Along similar lines, the concept of the “*cisgene*” (as opposed to *transgene*) has emerged. Schouten *et al.* (2006a) defined a *cisgene* as a gene, including its native promoter, terminator, and intron(s), all in normal sense orientation, that is transferred through transformation technology from one plant to a close relative. Critically, the distinction these authors made between a *cisgene* and a *transgene* is that the former can be accessed by plant breeders through conventional breeding approaches, while that latter cannot. Thus, Schouten *et al.* (2006a) defined the genetic relatedness of donor and recipient solely on the basis of crossability rather than on a traditional species concept as proposed by Nielsen (2003). Among the genes isolated from potato species and used to transform cultivated potato (Table 3) disease resistance genes *Gpa2*, *Gro1*, *R1*, *R3a*, *RB*, *Rpi-blb2*, and *Rx1* fit the proposed definition of *cisgene*. Schouten *et al.* (2006a) argued that *cisgenes* are fundamentally different from *transgenes* and that plants produced through *cisgenesis* are conceptually and biologically similar to plants produced through conventional breeding, despite the use of transformation technology. In fact, the authors opined that the use of *cisgenes* may be safer than conventional breeding approaches since linkage drag associated with the introgression of genes from unadapted germplasm through conventional approaches may result in unintended and frequently negative effects. Consequently, these authors have advocated for recognition of *cisgenesis* as a process distinct from *transgenesis* and for relevant alteration of regulatory restrictions (Schouten *et al.*, 2006a, b).

Defining the risk associated with genetically modified plants on the basis of genetic relatedness of donor and recipient, whether defined based on species classification or crossability, may resonate with the informed consumer and those opposed to transformation-based genetic modification of plants on ethical grounds. Results from a US consumer survey conducted by Lusk and Sullivan (2002) indicate that consumers are more willing to consume transformed foods if the *transgene* originated from a closely related species or from

within the same species. When asked if they would eat a vegetable transformed with a gene originating from a bacterium, only 23% of respondents said they would. Sixty percent of respondents indicated they would eat a vegetable transformed with a gene originating from a different vegetable. But favorable responses rose to 80% when a vegetable was transformed with a gene originating from the same vegetable (Lusk and Sullivan, 2002), corresponding to a *cisgenic* approach. Myskja (2006) explored moral arguments for the use of *cisgenes* (referred to in that study as “*intragenes*”) for crop improvement, advocating for increased scientific priority on *cisgenesis*, as opposed to *transgenesis*, both to reduce scientific uncertainty and potential risks associated with broad gene transfer and to respect the opinions of consumers opposed to broad gene transfer. However, the proposed distinction between *cisgene* and *transgenes* is not without debate, even among researchers (de Cock Buning *et al.*, 2006; Giddings, 2006; Schubert and Williams, 2006). Whether public perception will be significantly swayed by the argument that many of the genes inserted into cultivated potato do in fact originate from a potato species remains to be seen.

The results of the survey of Lusk and Sullivan (2002) also suggest that open evaluation of the costs and benefits associated with transgenic potato may further convince some skeptics that the approach has merit. Specifically, the researchers found that respondents were more accepting of transformation technologies when they perceived a direct health benefit to the consumer or the environment (Lusk and Sullivan, 2002). Participants were asked about their acceptance of a range of transformed crop plants including high carotene “golden” rice, corn transformed to reduce pesticide usage, corn transformed to reduce on-farm production costs, and bananas transformed to produce vaccines. Among these hypothetical transformed crops, respondents were most accepting of golden rice (86.9%) and bananas transformed to produce vaccines (86.2%). Fewer respondents accepted corn transformed to reduce pesticide usage (78.3%) or production costs (76.9%). Lusk and Sullivan (2002) concluded that transformation applications geared toward improvement of crops with obvious consumer or environmental benefits is more palatable to consumers.

The worldwide significance of potato as a food crop and the potential for transformation technologies using genes isolated from potato species to reduce the massive chemical inputs currently associated with potato production might be an effective counterbalance to resistance against genetically modified potato. Consider, for example, late blight. The disease is estimated to cause US\$5 billion annual losses worldwide both in yield losses and in chemical controls in potato and tomato (Kamoun, 2001). The recent emergence of *P. infestans* races resistant to the systemic herbicide metalaxyl (Fry and Goodwin, 1997) has necessitated the release of millions of tons of preventative fungicides into the environment each year. The late blight resistance genes *RB* and *Rpi-blb2* cloned from wild potato *S. bulbocastanum* impart broad-spectrum, pathogen race nonspecific foliar blight resistance (Song *et al.*, 2003b; Van Der Vossen *et al.*, 2003, 2005). These genes have been transferred to cultivated potato using bridge crosses (Hermsen and Ramanna, 1973) and somatic hybridization (Helgeson *et al.*, 1998), but commercially important potato cultivars from these efforts have not yet emerged. Using transgenic methods, researchers are now transferring these genes into commercially prominent potato cultivars. These efforts include development of selectable marker-free lines that carry only the transgene under control of its native promoter and lack antibiotic resistance genes or other nonpotato-derived sequence (i.e., *cisgenesis*). Transformed lines developed through these efforts have the potential to significantly reduce worldwide chemical inputs for potato production, but those opposed to genetically modified foods might reject transformed potato varieties carrying these genes solely on the basis of the method used to create them. The deployment of late blight resistant transgenic potatoes is not without risk and careful evaluation of the human health and environmental impacts of such activities are clearly warranted. But evaluation of transgenic technologies to combat late blight or otherwise genetically improved potato should also assess the risk of *not* using the technology. In the case of late blight, these risks include crop failure and potential starvation in areas of the world dependent on potato as a food source and lacking sufficient funds or infrastructure for routine preventative fungicide applications, and

financial impact on the grower and health impact to the consumer and the environment in regions of the world where fungicide applications for the prevention of late blight are commonplace. Such balanced assessment of transgenic technologies for potato improvement may play an important role in expanding consumer acceptance.

Potato is among the most important food crops in the world. Recent advances in molecular biology have yielded insights into the genetics of potato disease and insect resistance, nutritional and starch qualities of tubers, and genetic and physiological responses to environmental conditions. Several genes with potential to improve potato have been cloned from a variety of species. With ongoing efforts to sequence the entire potato genome, the near future is likely to see the cloning of many more genes from the approximately 200 potato species. Improved transformation technologies, including approaches for potato transformation without introducing selectable marker genes, are emerging. While current processor and consumer resistance to transformed potato represents a social barrier for commercialization of transgenic potato in the near future, research on transgenic potato is likely to continue and the potential for using transformation technologies for the improvement of potato remains high.

1. INTRODUCTION

1.1 History, Origin, and Distribution

The sweet potato, *Ipomoea batatas* (L.) Lam, is an important root crop supporting millions of people throughout the tropical regions of the world. Originally, sweet potato was domesticated in tropical South America from where it had spread to the South Pacific in prehistoric times. However, it is a relatively recent migrant in the countries where it now has the greatest importance. European traders and colonists brought the crop to Africa, Asia (Austin, 1988), and the western Pacific. Spanish explorers are believed to have taken the sweet potato to the Philippines and East Indies, from where it was soon carried to India, China, and Malaya by the Portuguese voyagers. It reached China, the world's number one sweet potato producer (88.9% of the world production) (FAO, 2004), in 1594 and Papua New Guinea (PNG), where it is a staple crop, sometime between 1600 and 1700. From China, it was introduced around 1700 to Japan, where it is now the third most important food crop. Rwanda, now one of the highest per capita consumers of sweet potato, began cultivating it only in the 18th century. Recently, the use of molecular markers provided evidence that Central America is the primary center of diversity and most likely the center of origin of sweet potato based on the richness of its wild relatives (Haung and Sun, 2000). One of the studies on the assessment of genetic diversity by

using amplified fragment length polymorphism (AFLP) marker advocated natural dispersal to be one of the key factors for the existing diversity of sweet potato (Rossel *et al.*, 1999–2000). Sweet potato is the seventh most important food crop worldwide (Jabsson and Raman, 1991) and is grown in 111 countries, particularly in Asia, Africa, and South America.

1.2 Taxonomy, Habit, Habitat, Genome Size, and Cytological Feature

Sweet potato, *I. batatas* (L.) Lam., belongs to the morning glory (Convolvulaceae) family. *Ipomoea* is derived from the Greek meaning worm bindweed. *Batatas* is the aboriginal American word for potato. Sweet potato is the only member of the genus *Ipomoea* whose roots are edible. Despite its name, sweet potato is not related to potato. Potato (*Solanum tuberosum*) is a member of the Solanaceae family, which also includes tomatoes, peppers, and eggplant. Unlike potato, which is a tuber, or thickened stem, sweet potato is a storage root. Sweet potato is an herbaceous and perennial plant. However, it is grown as an annual plant by vegetative propagation using either storage roots or stem cuttings. Its growth habit is predominantly prostrate with a vine system that expands rapidly horizontally on the ground. Also, depending on the length of internodes and frequency of branching, cultivars may be described as erect, semierect, spreading, and very spreading.

The most common type of sweet potato found in the US markets is the “moist-fleshed” type, red-skinned with dark-orange flesh. Dry-fleshed types of *I. batatas* (yellow, ivory, or white flesh) are popular among both Caribbean and Asian shoppers, especially on the US East Coast, and are sometimes sold under the Cuban name of *boniato*. “Boniato” is also the name of a specific cultivar.

Family	Convolvulaceae
Tribe	Ipomoeae
Genus	<i>Ipomoea</i>
Subgenus	<i>Quamoclit</i>
Section	Batatas
Species	<i>Ipomoea batatas</i> (L.) Lam.

Some consumers call sweet potato as “yams”. “Yam” (from the Yoruba word *iyama* (to eat)) is a term applied colloquially to the moist, orange-fleshed type of sweet potato. The true yam (*Dioscorea* spp.), a tuberous climbing vine not grown commercially on the US mainland, is naturalized in parts of the Upper South (chiefly *D. japonica*).

1.3 Karyotype and Cytology

The cultivated varieties of *I. batatas* display an important morphological polymorphism (Sihachakr and Ducreux, 1987). Among the species within the genus *Ipomoea* series Batatas, 13 are considered to be closely related to sweet potato (Austin, 1987), but the wild ancestor of this plant is still not identified. Several hypotheses have been put forward to explain the origin of sweet potato. It was thought to be originated from the diploid *I. leucantha* Jacq., from which tetraploid *I. littoralis* Blume was derived by polyploidization (Nishiyama, 1971).

Recently, Srisuwan *et al.* (2006) have studied the origin and evolution of sweet potato and its wild relatives through cytogenetic approaches. They studied the distribution and organization of 5S and 18S-5.8S-26S rDNA (ribosomal DNA) in ten varieties of hexaploid *I. batatas*, five accessions of tetraploid *I. trifida*, and six related species (five diploids, *I. trifida*, *I. triloba*, *I. tiliacea*, *I. leucantha*, and *I. setosa* and one tetraploid, *I. tabascanana*), by using fluorescence *in situ* hybridization. They concluded, based on chromosome morphology, that tetraploid *I. trifida* might be the progenitor

of *I. batatas*, and *I. tabascanana* might be the interspecific hybrid between these two species.

1.4 Economic Importance

Versatility and adaptability of sweet potato have given a rank to it as the world's seventh most important food crop following wheat, rice, maize, potato, barley, and cassava. It is adaptable to a wide range of climatic and soil regimes and is normally grown from 40° N to 32° S; from sea level to 9000-ft. (2743 m) elevation in areas where average temperature is 23.8°C or more with a well-distributed annual rainfall of 30–50 in. (0.76–1.27 m) and an abundance of sunshine. The more diversified utilization of sweet potato in Asia and Africa surely contribute to the improvement of local economies. Aside from being a subsistence crop, sweet potato makes a large contribution to livestock production in many areas. Nearly half of the sweet potato produced in Asia is used for animal feed, with the remainder being primarily used for human consumption, either as fresh or processed products. In contrast, although African farmers produce only about 7 million tons of sweet potatoes annually, most of the crop is cultivated for human consumption. African yields are quite low, about a third of Asian yields, indicating huge potential for future growth. Latin America, the original home of sweet potato, produces a mere 1.9 million tons annually. In the densely populated, semi-arid plains of eastern Africa, sweet potato is called *cilera abana* meaning “protector of the children”. This title alludes to the vital role it fulfills in thousands of villages, where people depend on the crop to combat hunger. Six sweet potato varieties that tolerate salt and drought (Yarada, Nacional, Tacna, Caplina, Atacama, and Costanero) were released by the Universidad Nacional Jorge Basadre from Tacna, Peru in 1992. The International Potato Center (CIP) reported that the share used as feed in Asia jumped from 14.5% in 1961–1963 to 44% in 1993–1995. Over 95% of the global sweet potato crop is produced in the developing countries, where it is the fifth most important food crop in terms of fresh weight. According to FAO's 1998 State of the World's Plant Genetic Resources, there are nearly 32 000 accessions held in gene banks around the world. The largest and most diverse collection is held at CIP, Peru.

Sweet potato has high content of carbohydrates and can produce more edible energy per hectare per day than wheat, rice, or cassava. The yellow-orange fleshed varieties provide particularly high quantities of vitamin A and C. The leaves can also be eaten, providing additional protein, vitamins, and minerals. The roots are most frequently boiled, fried, or baked. They can also be processed to make starch and a partial flour substitute. Industrial use of sweet potato for starch and other processed goods (e.g., alcohol, etc.) is more localized, but expanding. Thus sweet potato provides an additional source of cash for poor.

Sweet potato also possesses potent antioxidant properties and considered as antidiabetic and anti-inflammatory food. Our food ranking system also showed sweet potato to be a strong performer in terms of traditional nutrients. This root vegetable qualified as an excellent source of vitamin A in the form of β -carotene (Yoshimoto *et al.*, 1999; Konczak-Islam *et al.*, 2003; Haskell *et al.*, 2004; van Jaarsveld *et al.*, 2005) is a very good source of vitamin C and manganese, and a good source of copper, dietary fiber, vitamin B6, potassium, and iron. Both β -carotene and vitamin C are very powerful antioxidants that work in the body to eliminate free radicals. Free radicals are chemicals that damage cells and cell membranes and are associated with the development of conditions like atherosclerosis, diabetic heart disease, and colon cancer. Since these nutrients are also anti-inflammatory, they can be helpful in reducing the severity of conditions where inflammation plays a role, such as asthma, osteoarthritis, and rheumatoid arthritis.

In addition, sweet potatoes are a good source of vitamin B6, which is needed to convert homocysteine, an interim product created during an important chemical process in cells called methylation, into other benign molecules. Since high homocysteine levels are associated with an increased risk of heart attack and stroke, having a little extra vitamin B6 on hand is a good idea.

In South America, the juice of red sweet potatoes is combined with lime juice to make a dye for cloth. By varying the proportions of the juices, every shade from pink to purple to black can be obtained. All parts of the plant are used for animal feed. Sweet potato also has ethnomedical uses. The aerial roots are used as a galactagogue;

the leaves are used to treat diabetes (Yoshimoto *et al.*, 1999; Kusano *et al.*, 2001; Matsui *et al.*, 2001; Konczak-Islam *et al.*, 2003), hookworm, hemorrhage, and abscesses while the tuber is used to treat asthma. Recently, sweet potato products have also been considered to be used successfully in menus developed for space (NASA's advanced life support program) with added benefit of increased nutrient value and dietary variety (Wilson *et al.*, 1998; Ruminsky and Hentges, 2000; Bovell-Benjamin, 2007).

1.5 Traditional Breeding: Breeding Objectives, Tools and Strategies, and Achievements

Breeding of sweet potato through sexual means dates back to as early as 1904 (Tioutine, 1935), which then got momentum after inducing sweet potato to flower and set seed in 1937 (Miller, 1937). Since these early works, a vast amount of research has been carried out to improve overall sweet potato production, and the magnitude and ramifications of research has been astronomical.

Despite the fact that tremendous improvements have been made in sweet potatoes, very little progress has been made in terms of yield when compared to other crops. Worldwide losses of sweet potato include pre- and postharvest losses from insects, nematodes, and diseases, as well as a whole host of other factors (Jabsson and Raman, 1991). A poll of researchers in the developing countries found that the crop loss due to insects was the most important problem in the field. Although the importance of pest species varies regionally, weevils are the most important threat worldwide, particularly certain species of *Cyclas* (Wolfe, 1991). The sweet potato weevil, *C. formicarius*, is a major constraint to the production in many areas and is the single most important constraint in tropical regions (Horton and Ewell, 1991). Insect feeding can alone result in yield losses of 60–100% (Chalfant *et al.*, 1990). The level of natural resistance to insects is low and resistance does not seem effective at all under high weevil population pressure (Collins and Mendoza, 1991). Consequently, research into ways of reducing insect damage would be highly beneficial. Although sweet potato encompasses extensive genetic variability, it is difficult to

improve by conventional breeding because of being hexaploid ($2n = 6x = 90$), possessing cross-incompatible genes, and having low seed set (Lowe *et al.*, 1994). Furthermore, it is not possible to cross different lines in many cases owing to cross-incompatibility, as well as instability of hybrid offspring. It could, however, be possible to genetically modify sweet potato through the application of tissue culture and biotechnology and improve the crop in ways that cannot be achieved through conventional plant breeding programs based on sexual hybridization. Work is underway on the isolation and characterization of genes that will confer insect resistance. These genes are all derived from plants and include various types of protease inhibitors, α -amylase inhibitors, lectins, and other proteins with enzymatic functions. One of the main targets is to successfully introduce the cowpea trypsin inhibitor gene (*CpTI*) into sweet potato using an *Agrobacterium*-based approach, as *CpTI* has been demonstrated to confer tolerance to insect-pests when expressed in tobacco plants (Hilder *et al.*, 1987).

Conventional breeding methods in sweet potato have shown limited progress in the genetic improvement for, resistance to diseases (Clark, 1986), nematodes (Jones and Dukes, 1980), insects (Jones and Cuthbert, 1973), enhancement in protein contents, and nutritional quality (Water *et al.*, 1984). The success of plant genetic manipulation depends upon the effectiveness of *in vitro* regeneration system, which is highly genotype-specific in sweet potato (Gosukonda *et al.*, 1995). Considerable studies have been conducted in sweet potato tissue culture, but the lack of a reliable regeneration system has limited the application of biotechnology (Al-Juboory and Skirvin, 1991; Chee and Cantliffe, 1992; Sihachakr and Ducreux, 1993; Prakash, 1994; Lowe *et al.*, 1994). Thus, there is a critical need for screening of a large number of genotypes to test their regeneration potential and for their subsequent use in transformation studies. To overcome these limitations, breeders must incorporate novel approaches such as somatic hybridization and genetic transformation into conventional sweet potato breeding programs. Various gene delivery systems have been used to develop transgenic sweet potato concentrating on a specific trait. Three major gene delivery systems have been discussed in the following text, which demonstrates the efforts made in developing transgenic sweet potato

either by *Agrobacterium*-mediated transformation, electroporation, or biolistic approaches.

2. TRANSGENIC DEVELOPED AND DNA DELIVERY SYSTEMS

Several innovative methods have been developed to insert genes into the plant cell genome. However, electroporation and particle bombardment or biolistic gun are the most common techniques for direct DNA transfer. In addition, *Agrobacterium* plasmid is also a versatile vehicle to introduce genes into dicotyledonous plants. The above three approaches, for producing transgenic sweet potato (Dodds *et al.*, 1991; Prakash and Varadarajan, 1991; Newell *et al.*, 1995; Gama *et al.*, 1996; Murata *et al.*, 1997; Morán *et al.*, 1998), have been well documented. However, these methods had a limited success because of the lack of a reliable regeneration system and stable expression of introduced genes into the genome. The regeneration potential and prospects has been dealt in detail in the following text.

2.1 *Agrobacterium*-Mediated Transformation

Reports are available on transformation in sweet potato using *Agrobacterium*-mediated systems (Dodds *et al.*, 1991; Newell *et al.*, 1995; Gama *et al.*, 1996; Morán *et al.*, 1998; Song *et al.*, 2004; Luo *et al.*, 2006). The species of soil bacteria, such as *Agrobacterium tumefaciens* and *A. rhizogenes*, are capable of transferring discrete sequences of transfer-DNA (T-DNA) from their tumor-inducing (Ti) plasmid into the plant genome. The genes in the T-DNA are integrated into the plant genome and expressed, producing certain unique plant hormones called opines (Gasser and Fraley, 1989). These hormones cause an unregulated proliferation of callus tissue. The T-DNA is a specific segment in the Ti plasmid of *A. tumefaciens* and is delimited by borders (*cis*-acting sequences, T-DNA border and *trans*-acting function, *Vir* function) of repeated sequences. *Agrobacterium* is now frequently used as a vector for the introduction of foreign genes into plant cells. Among the available transformation methods reported in sweet potato, *A. tumefaciens*-mediated transformation is more successful and desirable

(Song and Yamaguchi, 2006). Since the presence of opine genes (*onc*-genes) in the T-DNA is incompatible with regeneration of the transformed cells into complete plants, preferably disarmed strains (devoid of Ti genes) are used as vectors. A major breakthrough in the development of Ti-plasmid binary vectors occurred as a result of deleting the phytohormone biosynthetic genes (Fraley *et al.*, 1985), and inserting marker genes from any organism, and introducing DNA cassette into plant genome using *A. tumefaciens* as a delivery system (Gasser and Fraley, 1989). In sweet potato, regeneration of *Agrobacterium*-mediated transformed callus has been reported (Al-Juboory and Skirvin, 1991; Carelli *et al.*, 1991). However, no regeneration in this callus was obtained. Also, the inherent problems of somaclonal variation associated with longer time in culture renders this approach less desirable than more direct methods of regeneration. Transformation in sweet potato, using *A. rhizogenes*-based vector, has been reported (Dodds *et al.*, 1991; Otani *et al.*, 1993). Hairy roots were induced on inoculated leaf discs, and shoots were subsequently regenerated from the hairy roots. However, this procedure involves the regeneration of plants from transformed hairy roots. It can be difficult to obtain phenotypically similar plants, due to the carryover of neoplastic genes from the root inducing-DNA (Ri-DNA) along with the gene of interest (Tepfer, 1984). Successful transformation of the cultivars Jewel and TIS-70357, using *Agrobacterium*-mediated transformation, has been reported by Prakash and Varadarajan (1991). But these experiments could not be repeated in other laboratories. However, Newell *et al.* (1995) reported successful regeneration of transgenic sweet potato plants through co-cultivation of storage root discs with *Agrobacterium*. Six regenerated plants expressed β -glucuronidase (GUS), cowpea trypsin inhibitor, and snowdrop lectin genes.

Sweet potato is more hardy and needs fewer nutrients from the soil than most other crops. However, increasing production is limited by the severe damage caused by pests and diseases. In many regions where sweet potatoes are produced in low-input agricultural systems, insect related losses may often reach 60–100% (Chalfant *et al.*, 1990). Sweet potato weevil (*Cylas formicarius*) is the major pest worldwide (Sutherland, 1986). Morán *et al.* (1998) cloned *cryIIIA* δ -endotoxin gene under the regulation of the cauliflower

mosaic virus (CaMV) 35S promoter and the tobacco mosaic virus (TMV) Omega fragment through *A. tumefaciens*-mediated transformation. Evaluations for the insecticidal capacity of transgenic plants were performed against sweet potato weevil both under controlled and field conditions. Another common problem with sweet potato is the attack of stem nematodes. It has been found that *oryzacystatin-I* (*OCI*) gene confers resistance to plant nematodes, such as *Meloidogyne incognita*, *Globodera pallida*, and *Heterodera glycines*. So far, nematode-resistant transgenic plants in rice, potato, and *Arabidopsis* have been produced (Urwin *et al.*, 1997; Atkinson *et al.*, 1998; Vain *et al.*, 1998). Scarce data are available on nematode resistance in sweet potato. Jiang *et al.* (2004) were able to produce transgenic sweet potato plants with *OCI* gene through *Agrobacterium*-mediated transformation by utilizing the strain LBA4404 with a binary vector PBinH and *neomycin phosphotransferase II* (*NPTII*) and *OCI* genes. Plant regeneration was successfully obtained from embryogenic calluses through somatic embryogenesis.

Among diseases, viral diseases of sweet potato are very prevalent and often seriously damaging to the plant. Efforts have been made to develop transgenic sweet potato with antiviral properties, lately by Min *et al.* (2006), where they have utilized a binary vector PGA748 under the control of CaMV 35S promoter, with *NPT* gene as a selectable marker, and introduced into *A. tumefaciens* LBA4404 for production of human lactoferrin is an iron-binding protein found in milk that plays an important role in the immune system response. It also prevents the growth of pathogens, exerts antibacterial, and antiviral properties and controls cell and tissue damage caused by oxidation, and facilitates iron transport (Arakawa *et al.*, 1999). One of the severe strains of viruses is sweet potato feathery mottle virus (SPFMV-S), which causes russet crack disease (Okada *et al.*, 2001). Resistance against SPFMV has been incorporated by Okada *et al.* (2002) where they were able to produce transgenic sweet potato, introducing hygromycin resistance (*hpt*) and SPFMV-S coat protein (*CP*) genes, which have shown a significant resistance to SPFMV-S. Such a production system for the virus-resistant transgenic sweet potato is useful in sweet potato breeding.

Efforts also have been made toward quality improvement by altering the expression of specific enzymes or enzymatic pathway. Kimura *et al.* (2001) successfully obtained transgenic sweet potato plants through *A. tumefaciens*-mediated transformation of full-length sense complementary DNA (cDNA) for sweet potato granule bound starch synthase I driven by the CaMV 35S promoter, demonstrating the possibility of altering starch composition in the tuberous root of sweet potato while increasing starch (amylose) content by RNA interference of the starch branching enzyme II (*IbSBEII*) gene. Similarly, Shimada *et al.* (2006a, b) constructed a double-stranded RNA (dsRNA)-interference vector on the basis of the registered cDNA of sweet potato *SBEII* encoding class A branching enzyme and introduced into sweet potato genome via *Agrobacterium*-mediated gene transformation for increased starch yield. In addition, Transgenic sweet potato plants were developed with increased content of linolenic acid through *A. tumefaciens*-mediated transformation by introducing a tobacco microsomal ω -3 fatty acid desaturase gene (*NtFAD3*) under the control of CaMV 35S/E12 ω promoter (Wakita *et al.*, 2001).

Another shift in trend has been observed for expression of pharmaceutical proteins. Plant-based expression of pharmaceutical proteins has proven as a cost-effective alternative to traditional large-scale production systems such as microbial fermentation, insect and mammalian cell cultures, and transgenic animals. Transgenic sweet potato has been developed by Berberich *et al.* (2005) with antidiabetic properties. Mouse *adiponectin* (encoding an antidiabetic protein) cDNA has been utilized for developing transgenic sweet potato via *Agrobacterium*-mediated transformation. Adiponectin is a 30-kDa protein exclusively produced and secreted from adipocytes and as a cytokine has been found to be linked to obesity, insulin resistance, and type-2 diabetes. Production of biologically active adiponectin in large scale is desirable for pharmaceutical applications.

2.2 Electroporation

Another approach for obtaining transgenic plants is via electroporation of naked plasmid DNA

in protoplasts/cells (Fromm *et al.*, 1985; Dhir *et al.*, 1991; Joersbo and Brunstedt, 1991). In electroporation, applying a controlled electric current to exposed membranes of protoplast, temporarily causes the membranes to become polarized. The effects of electric field on membrane permeability are relatively long lived (minutes) along with the duration of the applied pulse(s) (micromilliseconds). At a certain level (at electric current of 250–500 V cm⁻¹), the membranes show small pores, which allow entry or uptake of exogenous DNA, and these pores usually self-repair shortly after exposure to the current (Joersbo and Brunstedt, 1991). Okada *et al.* (2001) successfully obtained transgenic sweet potato lines resistant to the most serious disease of sweet potato called russet crack disease caused by SPFMV. They constructed an expression vector carrying the *CP* and hygromycin phosphotransferase (*hpt*) gene driven by CaMV 35S promoter and inserted into the sweet potato variety Chikei 682-11 by electroporation. The transgenic lines were shown to be highly resistant not only to the primary but also to the secondary infection of SPFMV-S. Most of the published works on electroporation was used to achieve transient (Mitchell *et al.*, 1998; Lawton *et al.*, 2000; Winfield *et al.*, 2001) and stable (Winfield *et al.*, 2001) transformation in protoplasts and to produce transgenic microcalli (Figure 1). But recovering transformed plants from these microcalli was a failure (Nishiguchi *et al.*, 1992). Successful example of plant regeneration, via somatic embryogenesis, and transient gene expression in sweet potato petiole protoplast has been demonstrated by Dhir *et al.* (1998) (Figure 2).

2.3 Particle Bombardment

Particle (microprojectile) bombardment of explants of sweet potato cultivars Jewel and TIS-70357 with a plasmid DNA containing GUS and *NPTII* genes, produced calli and roots which were positive for GUS (Prakash and Varadarajan, 1992). However, experiments to produce somatic embryos or to promote shoots from these transgenic calli has been unsuccessful so far (Prakash and Varadarajan, 1992; Prakash, 1994). However, recent studies have evidenced success in obtaining transgenic sweet potato plants. Among them is

Figure 1 Transient and stable expression of green fluorescent protein (GFP) in sweet potato mesophyll and petiole protoplasts using electroporation: (a) the yellow-green fluorescence of GFP is visible in transfected mesophyll protoplasts and red autofluorescence from chlorophyll ($\times 250$); (b) GFP expression in mesophyll protoplasts (protoplasts were viewed with a U-MNIBA filter set to eliminate the autofluorescence of chlorophyll, 400); (c) first division in a protoplast showing expression of GFP gene after 4 days in mesophyll protoplasts (400); (d) six- to eight-celled mesophyll protoplast-derived individual colonies expressing GFP gene; (e) 12–16 microcolonies expressing GFP after 2 weeks of culture; (f) microcalluses expressing GFP gene after 4 weeks of culture; (g) each green patch represents an individual transient expression event 48 h after bombardment of leaf tissues using a U-MNIBA filter to eliminate the autofluorescence of chlorophyll ($\times 250$); (h) several stable events showing the expression of GFP in leaf-derived callus [Reproduced from Winfield *et al.* (2001). © Springer]

Figure 2 (a) Plant regeneration from petiole protoplasts via somatic embryogenesis: (i) freshly isolated intact purified petiole protoplasts; (ii) Protoplast division after 5–6 days of culture; (iii) eight cell divisions; (iv) protoplast-derived microcalli on agarose beads after 8 weeks of culture; (v) protoplast-derived calli showing somatic embryoids; (vi) mature somatic embryos at various stages of development; (vii) well-developed plantlets regenerated from somatic embryos; (viii) protoplast-derived plants established in pots [Reproduced from Dhir *et al.* (1998). © Springer]

Figure 2 (b) transient gene expression in sweet potato protoplasts: (i) intense blue color indicating positive reaction of *gus* gene activity in electroporated protoplasts 24 h after X-Gluc (5-bromo-4-chloro-3-indolyl-beta-D-glucuronic acid) staining; (ii) expression of GUS in dividing protoplasts after 5–6 days of culture; (iii) cell colonies consisting of many cells showing intense blue color due to the expression of the *gus* reporter gene (protoplasts were electroporated and subcultured for 15 days and tested by a GUS histochemical assay)

herbicide-resistant sweet potato, where Yi *et al.* (2007) utilized biolistic method to introduce β -glucuronidase gene (*gusA*) and herbicide-resistant gene (*bar*) and reported successful transformation of the *bar* gene (Figure 3).

Besides insects, pests, and diseases, environmental stresses also play a significant role in crop production. Oxidative stress is one of the major factors causing injury to plants exposed to environmental stresses. Lim *et al.* (2007) have reported a remarkable achievement of enhancing the tolerance of transgenic sweet potato plants that express both CuZn superoxide dismutase (CuZnSOD) and ascorbate peroxidase (APX) in chloroplasts to methyl viologen-mediated oxidative stress and chilling. Particle bombardment has been used to express the genes of both CuZnSOD and APX under the control of an oxidative stress-inducible *SWAP2* promoter in the chloroplasts of sweet potato plants (referred to as SSA plants). Authors have advocated that SSA plants would be useful for commercial cultivation under unfavorable growth conditions. In addition, the manipulation of the oxidative mechanism in the chloroplasts can be applied to the development of various other transgenic crops with an increased tolerance to multiple environmental stresses. In recent experiments, Dhir *et al.* (unpublished) have also successfully expressed *GUS* gene in leaf explants of sweet potato through the use of particle bombardment (Figure 4).

2.4 Regeneration of Whole Plant

Sweet potato plant regeneration through tissue culture dates back to 1972 (see for review Henderson *et al.*, 1983) but is still considered to be difficult (Chee and Cantliffe, 1992; Chée *et al.*, 1992), especially from protoplast (Sihachakr and Ducreux, 1993), leaf (Wambugu and Henshaw, 1990), and somatic embryos. In order to improve the ultimate yield of regenerated whole plants via tissue culture, several investigators have utilized very young tissues as the explant source (Lowe *et al.*, 1994 and references therein). Various kinds of morphogenic responses reported for sweet potato tissues are described below.

2.4.1 Micropropagation: meristem and shoot tip culture

Meristem and shoot tips placed on Murashige and Skoog (MS) (Murashige and Skoog, 1962) culture medium allow formation of new shoots via axillary bud break, leading to the production of large number of shoots from a single explant in a short time. This technique has been applied in sweet potato to obtain virus-free clones for commercial purposes and also to obtain virus-free plant material in which viruses may be introduced to study the infection mechanism. Several researchers have reported establishment of

Figure 3 Sweet potato transformation, confirmation of transgenic events and transgenic plants growing in the greenhouse: (a) GUS expression in regenerating tissue; (b) GUS gene expression in leaf tissue (left, nontransformed; right, transformed); (c) Basta (0.3% v/v) painting on leaf tissue (left, nontransformed; right, transformed); (d) Chlorophenol Red assay on plantlets (left, nontransformed; right, transgenic plantlet) (the medium with red color indicates PPT sensitivity, whereas orange color indicates resistance); (e) 5 days after spraying Basta (0.3% v/v) to plants (left, nontransformed; right, transformed); (f) and (g) application of herbicide to sweet potato plants grown with a variety of weeds (f, before spray; g, 2 weeks after spray) (scale bars indicate 2 cm) [Reproduced from Yi *et al.* (2007). © Springer]

virus-free meristem cultures of many sweet potato cultivars (Elliott, 1969; Mori, 1971; Alconero *et al.*, 1975). Production of virus-free plants by a combination of heat treatment and shoot-tip culture has also been reported (Liao and Chung, 1979; Frison and Ng, 1981).

2.4.2 Organogenesis

Organogenesis is the formation and outgrowth of multiple shoots via callus or directly from explants and subsequent rooting to regenerate complete plantlets *in vitro* (Figure 5). Various studies have been conducted to optimize explant sources and a matching culture medium for sweet potato tissue culture (Hill, 1965; Henderson *et al.*, 1983). Gunckel *et al.* (1972) were the first to report the induction of roots and shoots

from storage root segments of the cultivar “Centennial” on MS medium. Similar finding were reported by other researchers (Hwang *et al.*, 1983). Shoot regeneration can be induced directly from adventitious roots either from shoot culture (Yamaguchi and Nakajima, 1972; Ozias-Akins and Perera, 1992) or from regenerated roots arising from tissue-cultured explants (Carswell and Lacy, 1984; Belarmino *et al.*, 1992). The level of regeneration in all cases was low, approximately one shoot per explant under optimal conditions.

Excised leaf tissue has also been used as an explant for producing callus, roots, and shoots (Sehgal, 1975). The capacity of leaves to produce callus was dependent on their maturity and the amount of callus was related to the degree of cuts given or the extent of injury caused (Sehgal, 1975). Also, Litz and Conover (1978) were able to induce callus from lateral buds and shoot apices,

Figure 4 Expression of *GUS* gene into different explants of sweet potato using particle bombardment mediated gene transfer technique [Reproduced from Dhir *et al.*, unpublished data]

Figure 5 Somatic embryogenesis, organogenesis, and plant regeneration from sweet potato explants [Reproduced from S. Dhir *et al.*, unpublished data]

which then produced roots and shoots. Wambugu and Henshaw (1990) obtained shoot buds from 4-month-old leaf-derived callus. Shoot regeneration from petiole explant of sweet potato has also been reported (Hwang *et al.*, 1983; Templeton-Somers and Collins, 1986; Xin and Zhang, 1987; Suga and Irikura, 1988; Gosukonda *et al.*, 1995). However, in all reports the percentage of regeneration was reported to be very low.

2.4.3 Somatic embryogenesis

An alternative approach to regenerating plants involves the induction of somatic embryos from somatic cells. Somatic embryos (Figure 5), considered to be of single-cell origin, are independent bipolar structures and are not physically attached to the tissue of their origin. These structures can further develop and germinate into plantlets through the events that correspond with the zygotic embryogenesis (McKersie and VanAcker, 1994). Somatic embryos have potential use as *in vitro* germplasm and can be used as artificial seeds. Although somatic embryogenesis has been achieved in sweet potato (Hwang *et al.*, 1980; Jarret *et al.*, 1984), but the success in regenerating plants is restricted only to a few cultivars. Somatic embryos were most efficiently induced in shoot tips and in each case, embryos developed directly from callus induced by 2,4-dichlorophenoxy acetic acid. The whole plantlets regenerated from these embryos were phenotypically identical to the parent plants (Jarret *et al.*, 1984; Liu and Cantliffe, 1984; Harrell *et al.*, 1993). Histological studies demonstrated embryogenic callus initiation from the periphery of the apical dome and from the youngest pair of the leaf primordia (Liu *et al.*, 1989). In most cases, sweet potato somatic embryos were found arrested at all stages of development and showed great variability in developmental patterns and morphogenesis (Chée and Cantliffe, 1988a, b).

An improvement in the production of embryos in suspension cultures was achieved by using alginate beads or sieving methods, which led to the release of polarized individual cell aggregates during callus fragmentation (Chée and Cantliffe, 1988a). In these cultures, up to 53% of somatic embryos were capable of regenerating into whole plants (Chee *et al.*, 1990). Embryos produced in

suspension cultures differed from mature seed-derived embryos in morphology and apparent lack of dormancy (Chee *et al.*, 1990). Development of sweet potato somatic embryos is highly genotype dependent (Sonnino and Mini, 1993). The use of somatic embryos in sweet potato as synthetic seed is limited by the production of large number of high-quality, somatic embryos. To compete commercially with the true seed or for efficient micro- and macropopagation system, somatic embryos must be able to germinate rapidly with high frequencies (Bornman, 1993). Successful production of synthetic seed in sweet potato needs more research to study the effect of several factors on induction, growth, development, and maturation of somatic embryos.

2.4.4 Anther culture

The main advantage of using haploids in a breeding program is the production of reliable homozygous lines in a short period of time (Alejar *et al.*, 1995). To date, true haploids have not been reported in sweet potato, but there have been a number of experiments using anthers as the source for callus tissue from which plantlets were developed. Callus tissue derived from anthers of sweet potato flowers has been obtained (Tsai and Lin, 1973a, b; Sehgal, 1978; Tsai and Tseng, 1979); however, the developed plantlets were not haploid. Also, techniques to conserve sweet potato germplasm *in vitro* have been developed (Jarret, 1989; Jarret and Florkowski, 1990; Kuo, 1991).

2.4.5 Protoplast culture

The development of protoplast isolation and culture techniques probably offer the most promising strategy for evolving new plant hybrids and varieties, especially in vegetatively propagated plants like sweet potato (Perera and Ozias-Akins, 1991). Reports on development of fertile sweet potato plants from protoplasts are limited. The successful isolation of sweet potato protoplasts from stem callus was first reported by Wu and Ma (1979). Later, Bidney and Shepard (1980) were able to produce callus from petiole protoplasts and leaf mesophyll cells of the cultivars Jewel and Centennial, but no shoot morphogenesis or

embryogenesis was observed. Protoplasts have been isolated from various tissues including petioles, stems (Otani *et al.*, 1987; Sihachakr and Ducreux, 1987; Perera and Ozias-Akins, 1991), and calli (Nishimaki and Nozue, 1985). In contrast, mesophyll tissues are considered recalcitrant to enzyme digestion (Otani *et al.*, 1987). Recently, Perera and Ozias-Akins (1991) and Ozias-Akins and Perera (1992) isolated protoplasts from mesophyll tissue and petioles and observed sporadic shoot formation from the protoplast-derived callus. Protoplasts were also isolated from high anthocyanin-producing callus of sweet potato by Nishimaki and Nozue (1985). The first report of successful plantlet, shoot/root formation from protoplasts, was presented by Sihachakr and Ducreux (1987) and later by Dhir *et al.* (1998). Thus, it is possible to regenerate plants from protoplast. However, there is a need for refinement of the current procedures to make them applicable across various genotypes.

3. FUTURE ROAD MAP

The application of new techniques for improvement of sweet potato crops, particularly including the exploitation of somaclonal variation, gene transfer by genetic transformation and somatic hybridization, requires the control of plant regeneration from tissue culture (Sihachakr *et al.*, 1997). The success of transgenic effort can only be achieved by optimizing a successful regeneration protocol. Tremendous success has been achieved in the gene transfer and regeneration of transformed plants in the last one decade. With the trend of technology moving in such a fast pace in genetic modification, releasing genetically modified crops into the environment brings unforeseen threats and potential risk of gene flow via pollen from crops to related wild species (Sossey-Alaoui *et al.*, 1996) with consequences such as the potential for development of resistant pests and outcrossing to weedy relatives. However, sweet potato is an asexually propagated, cross-incompatible plant with morning glory the only known natural hexaploid in its family. Thus, chances of cross-pollination of transgenic sweet potato plants with wild plants are very remote. Sweet potato could be considered as an excellent novel source of natural health-promoting compounds, such as β -carotene

and anthocyanins, for the functional food market, also, the high concentration of anthocyanin and β -carotene in sweet potato, combined with the high stability of the color extract make it a promising and healthier alternative to synthetic coloring agents in food systems (Bovell-Benjamin, 2007). Development of insect-resistant transgenic cauliflower plants expressing the trypsin inhibitor gene isolated from local sweet potato was accomplished by Ding *et al.* (1998). Starch and flour processing from sweet potato can create new economic and employment activities for farmers and rural households, and can add nutritional value to food systems.

Besides, recent advances and availability of cutting-edge technology for the expression or manipulation of multiple genes in plants is still difficult to practice. Although a small proportion of commercial genetically modified (GM) crops present “stacked” or “pyramided” traits, only a handful products have been developed by introducing three or more novel genes (Haplin, 2005). A number of conventional and more novel techniques already exist for the stacking of genes and/or traits in transgenic plants. No single method is, as yet, ideal and individual methods may suit some purposes more than others.

In the postgenomic era, we have gained extraordinary information and understanding of various metabolic pathways and pinpointing the individual genes involved in a specific response or trait. This will provide foundation for developing resilient crops with potential of multiple stress tolerance, enhanced nutritive value, medicinal and nutraceutical importance.

It is quite often seen that transgenics with the potential of sustainable production capabilities fail in enabling a fully sustainable agriculture. Genetic traits that have a higher potential for promoting a sustainable agriculture have been precluded from development for a number of reasons. These include the lack of Environmental Protection Agency (EPA) and United States Department of Agriculture (USDA) regulatory policies that explicitly promote sustainable traits; the structure of the agricultural biotechnology industry, which is dominated by agricultural chemical companies; and patent law and industry policies that prohibits farm households from saving transgenic seed and tailoring transgenic crops to their local environmental

conditions—ecological, social, and economic (Hubbell and Welsh, 1998). There is need to develop sustainable system for potential transgenic technologies through regulatory approvals assuring the public about safety and stability of genetically modified products. The increasing world population and changes in consumption patterns may necessitate significant agricultural intensification in the next 50 years (Khush, 2001; Tilman *et al.*, 2001). Unless crop yield is improved and release of fertilizers and pesticides from crop lands is reduced, such intensification could aggravate contamination and perturbation of managed and natural ecosystems, ultimately harming biodiversity and public health (Pimentel and Raven, 2000; Khush, 2001; Tilman *et al.*, 2001; Huang *et al.*, 2002). It seems highly inevitable that future agricultural and, ultimately, also natural ecosystems will be challenged by the large-scale introduction of entirely novel genes and gene products in new combinations at high frequencies all of which will have unknown impacts on their associated complex of nontarget organisms, i.e., all organisms that are not targeted by the insecticidal protein. In times of severe global decline of biodiversity, proactive precaution is necessary and careful consideration of the likely expected effects of transgenic plants on biodiversity of plants and insects is mandatory.

1. INTRODUCTION

1.1 Biology of Cassava

Cassava (*Manihot esculenta* Crantz) is a member of the dicotyledonous family Euphorbiaceae (Alves, 2002). The genus *Manihot* has been reported to have about 100 species of which *M. esculenta* is the only agronomically important species. Domesticated cassava is believed to have resulted from an interspecific cross of two wild species and to have occurred in southwestern Brazil (Olsen and Schaal, 1999). Genetically, cassava is an allotetraploid. The genome size is approximately 760 Mb (mega bases), distributed on 18 chromosomes with a GC content of 43.7%.

1.1.1 Plant architecture

Cassava grows between 1 and 4 m in height (Figure 1a). The branching pattern is characterized by sympodial growth wherein the main stem is typically divided into two to four branches with multiple subbranches. Cassava leaves are lobed with palmate veins. The number of leaf lobes ranges from three to nine. Leaves produced at the time of flowering are reduced in size and lobe number. The leaves have an alternate arrangement with a 2/5 phyllotaxy. Mature leaves are glabrous and are surrounded by two stipules at the base. The adaxial leaf surface is characterized by a

waxy epidermis that gives it a shiny appearance. The stomata are located mainly on the lower leaf surface (Cerqueira, 1989). Only 2% of the 1500 cultivars studied had stomata on their adaxial surface (El-Sharkawy and Cock, 1987). Stomata are functional on both sides of the leaf, but those on the upper surface of the leaf are larger (Cerqueira, 1989).

When present, flowers are typically located at the junctures between branches. This developmental series has been termed reproductive flowering (Alves, 2002). Cassava is monoecious producing both male (staminate) and female (pistillate) flowers on one plant. The staminate flower is located on the lower part of the branches opposed to the pistillate flower on the upper part. The pistillate flowers are more numerous than the staminate flowers. The female flowers open 1–2 weeks before the male flowers on the same inflorescence. The plants are, therefore, prone to cross-pollination, which might explain the high level of heterozygosity in cassava (Alves, 2002). The flowers lack a corolla or calyx but have a perianth with five sepals of varying color (yellow, red, purple) depending on cultivar. The male flower is about half the size of the female and has 10 stamens (Alves, 2002). The pollen is yellow or orange and ranges in size from 122 to 148 µm (Ghosh *et al.*, 1988). The female flower has a 10-lobed basal disk with a tricarpeal ovary having six ridges. The three locules each contain one ovule, which matures into carunculate seeds. The seed coat is smooth and dark brown mottled with gray.

Figure 1 (a) Cassava plants growing in the field, (b) cassava root freshly harvested from the field [Source: IITA website, <http://www.iita.org>]

Little is known about the control of flowering in cassava (Alves, 2002). Many cultivars are known not to flower. Flowering can start 6 weeks after planting but the time it takes to flower is a function of the cultivar and the environment. Moderate temperatures (approximately 24 °C) are known to be conducive for flower initiation. Photoperiod also is known to affect flowering. Flower initiation occurs best at photoperiods above 13.5 h (Keating *et al.*, 1982).

The main carbohydrate storage organ of cassava is the root and each plant may have multiple

storage roots (Figure 1b). This pattern of rooting is characteristic of crops that are propagated by stem cuttings. Adventitious roots arise from the base of the cut surface or from subterranean buds. Some roots develop into storage roots while others will remain fibrous and serve to supply water and nutrients to the plant. The cassava storage root is not anatomically a tuber or stem due to the organization of the phloem and xylem (Wheatley and Chuzel, 1993). The fully developed cassava storage root can be subdivided into three distinct sections: the periderm (bark), peel, and

the parenchyma. The parenchyma is the edible part, which consists mainly of starch and makes up about 85% of the total root mass. The parenchyma is interspersed with xylary tissues, however, most of these are in the central core (Wheatley and Chuzel, 1993). The peel is made up of sclerenchyma, cortical parenchyma, and phloem and accounts for approximately 11–20% of the root weight (Barrios and Bressani, 1967). The periderm comprises about 3% of the total root mass and is a thin layer that can be readily removed from the exterior of the root. The size and shape of roots is contingent on the cultivar and environmental factors (Wheatley and Chuzel, 1993).

1.1.2 Physiology and agronomy

Cassava has many agronomic traits that are desirable for high-yielding crops. For a C3 plant it has an unusually high photosynthetic rate ($43 \mu\text{M m}^{-2} \text{s}^{-1}$) as well as a broad temperature range (20–45 °C) for carbon assimilation (Edwards *et al.*, 1990; Angelov *et al.*, 1993). In addition, it does not light saturate at high irradiance levels, the leaves maintain good stomatal control even when drought stressed, and it has a chlorenchymatous bundle sheath cell layer; traits similar to those of high-photosynthetic C4 plants (Edwards *et al.*, 1990; Angelov *et al.*, 1993). Significantly, cassava has the highest rate of sucrose production of any plant measured (Angelov *et al.*, 1993). Forty-five percent of the carbon fixed is converted into sucrose in less than 1 min. This rate is sixfold greater than for C4 species such as *Flaveria*. In addition, the high rate of sucrose synthesis does not vary with respect to leaf age, light intensity, or temperature (between 21 °C and 32 °C).

The distribution of dry matter in cassava is dependent on the age of the plant. During the first 60–75 days following planting dry matter accumulation is mainly in the leaves. However, after the fourth month, more dry matter is accumulated in the storage roots than the rest of the plant (Howeler and Cadavid, 1983; Tavora *et al.*, 1995). At 12 months of growth, the dry matter is present mainly in the storage roots followed by stem and leaves. The time for the maximal accumulation of dry matter depends on the cultivar and the environment. The growth

phase in high latitudes is 4–6 months (Lorenzi, 1978) and 7 months for high altitudes (Oelsligle, 1975). In the tropics, where growth is faster, the maximum rate of dry matter accumulation is between 3- and 5-month age (Howeler and Cadavid, 1983).

All cassava organs apart from seeds contain cyanogenic glycosides. Cultivars with less than 100 mg CN equivalents per kilogram fresh weight (kgfw) in their roots are called “sweet” while cultivars with 100–500 mg CN equivalents per kilogram are classified as “bitter” cassava (Wheatley *et al.*, 1993). The most prevalent cyanogenic glycoside is linamarin (95%) with lesser amounts of lotaustralin. The total amount of cyanogenic glycoside is dependent on cultivar, cultural practice, environmental conditions, and plant age (McMahon *et al.*, 1995). Linamarin is synthesized in the leaf and transported to the roots (Wheatley and Chuzel, 1993; Siritunga and Sayre, 2003). The hydrolysis of linamarin and breakdown of acetone cyanohydrin by hydroxynitrile lyase (HNL) or elevated pH (>5.0) leads to the release of HCN, which is poisonous (Cooke and Coursey, 1981). Compartmentalization of linamarase in cell walls and laticifers and linamarin in the vacuole guards against the release of HCN in intact plant tissues (McMahon *et al.*, 1995). Processing of cassava roots brings enzyme and substrate together leading to the hydrolysis of linamarin and breakdown of acetone cyanohydrin to produce cyanide (Mkpong *et al.*, 1990; Wheatley and Chuzel, 1993; McMahon *et al.*, 1995; White *et al.*, 1998).

Postharvest deterioration is a major constraint for marketing fresh cassava roots. Roots are very perishable and deteriorate within 24–72 h after harvest. This deterioration is manifested by the production of phenolic compounds whose polymerization leads to the discoloration of the roots (Wheatley and Chuzel, 1993). This process is oxygen dependent and can be inhibited by placing the roots in an anaerobic environment (Wheatley and Chuzel, 1993; Reilly *et al.*, 2007). The earliest events are mediated by the production of reactive oxygen species (ROS), which is followed by expression of genes involved in ROS metabolism (Reilly *et al.*, 2007). Secondary deterioration is associated with microbial infection of damaged tissues (Wheatley and Chuzel, 1993).

1.2 How Cassava Came to Africa

Botanical, genetic, and archeological evidence supports the South American origin of cassava, pointing to the Amazon region as the center of cassava domestication (Olsen and Schaal, 1999; Hillocks, 2002). Olsen and Schaal (1999) took advantage of the high variations in the noncoding sequence of the glyceraldehydes 3-phosphate dehydrogenase (*G3pdh*) gene to determine the center of origin and genetic diversity of cassava. They determined that cassava was domesticated from wild *M. esculenta* populations along the southern border of Brazil near Paraguay. Portuguese navigators took cassava with them from Brazil to West Africa in the 16th century (Jones, 1959) and then later to East Africa (Jennings, 1976). Even though cassava was grown in Fernando Po in the Gulf of Benin and around the Congo River in the 16th century, cassava's dispersal into West Africa did not take place until the 20th century (Hillocks, 2002). Cassava was initially grown mainly in the coastal areas. The inland spread of cassava cultivation was by African traders who were drawn to cassava for its fabled characteristic of providing security against famine. Cassava is now grown in most African countries especially south of the Sahara desert. Realizing the importance of cassava, the International Institute of Tropical Agriculture (IITA) was established with its headquarters in Ibadan, Nigeria in 1972 under the guidance of the Consultative Group on International Agricultural Research (CGIAR) to oversee the development of the crop in Africa. Together with Centro Internacional de Agricultura Tropical (CIAT) in Colombia, IITA has the global mandate for cassava improvement (Hillocks, 2002).

1.3 Cassava Production

Although cassava is native to the Amazon region, Africa now produces more cassava than the rest of the world combined. Africa's largest producers of cassava are Nigeria (35%), Democratic Republic of Congo (19%), Ghana (8%), Tanzania (7%), and Mozambique (6%). The top producers in Africa have increased their production greatly in the past two decades especially Nigeria (22–35%) and

Ghana (4–8%) (IITA, 1997). Other countries are on the decline.

The increases in production of cassava have come as a result of increase in the area of land cultivated as opposed to increase in yield per hectare. Average yields have increased by 33% in the past two decades while the cultivated land for cassava increased by 70% during the same time period (IITA, 1997). In Africa, cassava yield declined 1.2% to 0.6% in the past decade. Only Ghana has increased yield from 1990 to 1995. According to the survey conducted by the Collaborative Study of Cassava in Africa (COSCA), funded by Rockefeller Foundation, the main reason for the increase in cultivation is response to famine, hunger, and drought. This confirms the value of cassava as a security crop (Hillocks, 2002).

1.4 Economic Importance

1.4.1 Cassava starch

Starch is the most important form of carbon reserve in plants with respect to the amount produced, its distribution among different plant species, and its commercial importance (Martin and Smith, 1995). Starch comprises different polymers of glucose arranged in a three-dimensional, semicrystalline structure called the starch granule. Starch is composed of two types of glucan polymers: amylose and amylopectin (Martin and Smith, 1995). Amylose is made up of linear chains of α (1,4)-linked glucose residues, which are typically about 1000 residues long. It may have one α (1,6)-linkage per 1000 residue and makes up about 30% of total starch (Okita, 1992; Martin and Smith, 1995; Smith *et al.*, 1995). On the other hand, amylopectin consists of highly branched glucan chains and accounts for about 70% of total starch in most plants. Chains of about 20 α (1,4)-linked glucose moieties are joined by α (1,6)-linkages to other branches. Some branches of amylopectin are not substituted on the number 6 position and are called A chains. These are α (1,6)-linked to inner branches called B chains, which may be branched at one or more points. A single chain per amylopectin molecule has a free reducing end, the C chain (Kainuma, 1988; Smith and Martin, 1993; Martin and Smith, 1995).

The phosphorylation of starch is almost universal in plants (Blennow *et al.*, 2002). Glycogen, which is the analog of starch in animals, also contains phosphate groups, an indication that phosphorylation is a requirement for storage α -glucan metabolism (Vikso-Nielsen *et al.*, 2002). However, the level of starch phosphorylation varies among plants. Phosphorylation in cereal starch is low (less than 1 nM Glc6P/mg starch). Cassava starch has 2.5 nM Glc6P/mg starch, a low level of phosphorylation. In contrast, potato starch is highly phosphorylated (8–33 nM Glc6P/mg starch) (Blennow *et al.*, 2000, 2002). The phosphate groups are bound mainly to the amylopectin moiety of starch as monoesters at the C-6 and C-3 positions of glucose units (Bay-Smidt *et al.*, 1994; Blennow *et al.*, 2002). The phosphorylation of starch serves to increase the hydration capacity following gelatinization. Phosphorylation of starch prevents its crystallization and affects the viscosity of the final product. Engineering crop starch for higher phosphate content is important because it reduces expensive and environmentally hazardous chemical processing by the industries (Blennow *et al.*, 2002).

Cassava starch is stored in the amyloplasts of thickened roots. The starch content of cassava roots ranges from 74% to 85% of the dry weight (Rickard *et al.*, 1991; Munyikwa *et al.*, 1997). Cassava starch granules are round, flat on one side, and contain a conical pit, which extends to well-defined, eccentric helium, ranging in size from 5 to 40 μ m (Moorthy, 1994; Munyikwa *et al.*, 1997). An 18-month study of the growth of cassava granules indicated that growth continues up to the 6th month. No further growth was observed after 6 months (Moorthy and Ramanujan, 1986).

The amylose content of cassava starch is 15–26% (Ketiku and Oyenuga, 1972; Kawabata *et al.*, 1984). Starch is classified into three types based on different x-ray diffraction patterns, namely, A, B, and C. Cassava starch comprises mainly the A-type pattern that is characteristic of cereal starches (Guiltbot and Mercier, 1985). This A-type pattern is characterized by a closely packed double helices compared to the more open B-type arrangement. Raw cassava starch contains 0.08–1.54% crude fat, 0.03–0.6% crude protein, and 0.75–4% phosphorus (Soni *et al.*, 1985; Munyikwa *et al.*, 1997).

1.4.2 Cassava foods

Cassava serves as the main staple food for more than 500 million people in the tropical and subtropical regions of the world (Balagopalan, 2002). It also contributes significantly to the livelihood of these people. Cassava is eaten raw in Africa and other parts of the world where it is grown, after removing the skin. However, the cultivars that are eaten raw are the “sweet cultivars”, which have low cyanogenic glycoside content. The cultivars that have high cyanogenic glycoside content are processed and cooked before consumption (Balagopalan, 2002).

Cassava is used as food in various ways across the regions of the world. In South America, cassava tubers are grated and pounded into pulp. The dewatered pulp is often shaped into pies and cakes, wrapped in leaves, and baked on fire. In West Africa, cassava roots are fermented in a pot for 4–7 days, boiled, and pounded into *fufu* and eaten with vegetable soup supplemented with fish and meat (Lancaster *et al.*, 1982).

In Liberia, cassava is made into *dumby*, which is prepared by placing boiled cassava roots in mortar followed by pounding. Following pounding, the *dumby* is cut into pieces and put in soup supplemented with vegetables or meat. It is then swallowed whole. Cassava is also made into *farina* in South America and West Indies. *Farina* is prepared by removing the skin of the cassava root and grating. The mash is then depulped, sieved, and roasted in a slow fire. It could then be stored for several months and can be eaten as a cereal and in combination with other foods (Omole, 1977).

Cassava macaroni is prepared by blending cassava flour, groundnut flour, and wheat semolina in the ratio 60:12:15. It is enriched with 12% protein. The food is used to feed children because of its high protein content (Balagopalan, 2002).

In Ghana, Nigeria, Guinea, Togo, and Benin, *gari* is one of the most important cassava foods. Cassava roots are skinned, grated, and dewatered in sacks made from jute fibers and allowed to ferment for 2–4 days. This is followed by sieving to remove fibers from the roots. It is then fried in shallow iron pans and stirred continuously until it becomes dry and crisp. Palm oil is added sometimes during frying to prevent burning and also as a source of carotene in the food. *Gari* is prepared with boiling water to make a thick paste.

Cassava is also used in preparing fast food. It is used in preparing wafers, and made into fried chips, cakes, and doughnuts (Balagopalan, 2002).

Cassava is also important in animal feeds. Various parts of the plant such as leaves, stem, and roots are used to feed animals. The high energy value of cassava makes it a good source of carbohydrate in animal diets (Omole, 1977). However, roots have low protein content. This shortcoming is often overcome by supplementing it with soya, which is rich in protein.

Fresh roots are used in feeding farm animals such as cattle, goats, and sheep in the developing countries. Sometimes, the roots are boiled before feeding animals. Feeding livestock with fresh roots might cause cyanide toxicity depending on the level of cyanogenic glucosides in the roots. It has been reported that replacement of cereals with cassava up to 50–100% did not affect the milk quantity and quality in dairy animals (Mathur *et al.*, 1969). In some cases, higher milk yield has been reported up to 19.5% as a result of increased energy from cassava (Balagopalan, 2002).

Cassava leaves are used as forage in many developing countries especially in the dry season when other feeds are scarce. There is some opposition to the use of cassava leaves as forage, however, for fear of cyanogenic poisoning of the livestock (Balagopalan, 2002).

1.4.3 Cassava and industry

Cassava is an important commodity in industry mainly because of its starch, which is used in the production of various items. Cassava starch is used in the production of adhesives and a variety of other compounds (Balagopalan, 2002). Gums are made from cassava starch by heat treatment. Other varieties of adhesives are made from cassava starch by the addition of chemicals (Cock, 1985; Balagopalan, 2002).

Cassava gum, made without additives, is produced by cooking cassava starch with water. Preservatives may be added later if needed. This type of gum is used in bill pasting, making bags, and in the tobacco industry. Copper sulfate may be added to the paste to prevent microbial damage. Cassava starch is used for paste production because of its cohesiveness and clarity. Cassava starch is preferred for food packaging over other

types of starch because of its bland taste (Cock, 1985; Balagopalan, 2002).

The cassava gums containing chemicals are made by the addition of calcium chloride, magnesium chloride, borax, urea, and carboxymethyl cellulose during the process of gelatinization. The chemicals increase viscosity, flow ability and are used for controlling hydration. Such gums are used in the lamination of papers, production of wallpapers, and pasting labels (Abraham, 1996; Balagopalan, 2002).

Cassava starch is also used in production of dextrans. An aqueous solution of dextrin is used for bonding similar and dissimilar surfaces. Dextrans are not as strong adhesives as starch films but are preferred to starch because they can be used at higher concentrations than starch, which accelerates drying. Dextrans are used as envelope gums, bottle-labeling adhesives, postage stamps adhesives, in making cardboard boxes, and photographic mounting materials (Cock, 1985; Trim *et al.*, 1996; Balagopalan, 2002).

Glucose and dextrose, products of starch hydrolysis, are liquefied into sugar syrups. The syrup can be used in making confection and in the pharmaceutical industry. Cassava starch is also used in making fructose syrup and fructose crystals, which are used in the substitution of sucrose, glucose, and synthetic sweeteners. Fructose is 1.7 times sweeter than sucrose and 4 times sweeter than glucose (Abraham, 1996). Cassava starch is also used in the manufacture of maltodextrin, which substitutes for glucose as a sweetener. It is also used as a thickening agent (Balagopalan *et al.*, 1988; Balagopalan, 2002). Cassava starch oxidized with hypochlorite or chlorine is useful in the paper industry because of its low viscosity, film strength, and clarity in making glossy papers. These starches are also used in the textile industry for sizing warps of cotton and spun rayons and for laundry finishes. Cationic starches made by treating starch with amino, imino, ammonium, sulfonium, or phosphonium groups are used in the paper industry to provide glaze and strength to paper (Cock, 1985; Abraham, 1996; Trim *et al.*, 1996).

Cassava starch is used in blending synthetic polymers to give it biodegradable characteristics. Cassava starch, because of its low swelling and gelatinization temperature, is easily saccharified

to simple sugars. These simple sugars are used in the production of sugar alcohols such as sorbitol, mannitol, and maltol. Sorbitol can be used to replace glycerin in the production of toothpaste, cosmetics, and oil-based paints. It is also used as a raw material in the production of ascorbic acid (Ren, 1996). Mannitol has a wide range of applications in medicine as a dehydrating agent in blood vessel diastolic preparations. Mannitol is also used in the treatment of cerebral thrombosis and other circulating disorders and in the production of polyester, polyethylene, and solid foam plastics. Maltol, a food flavoring agent, is used in the confectionery industry (Ren, 1996).

2. CASSAVA BIOTECHNOLOGY

2.1 Plant Tissue Culture and Regeneration

Cassava, a very important crop in the tropics, is very difficult to breed by classical genetics. It takes 10 years to generate a new cultivar by conventional breeding (Alves, 2002). This is in large part due to inconsistent flowering coupled by poor seed set. Cassava is also heterozygous and clonally propagated (Jennings and Iglesias, 2002). In this circumstance, genetic engineering becomes attractive for substituting plant breeding for cassava improvement. One of the requirements for the generation of transgenic cassava is an efficient and reproducible plant regeneration system. Nearly all parts of cassava plant have been used to establish *in vitro* cultures (Roca, 1984).

Somatic embryogenesis is the method of choice for cassava regeneration. Explants have been mostly restricted to young leaves and shoot meristems. Somatic embryos have been induced from cassava young leaf lobes and cotyledons. Plants have also been regenerated from these tissues (Stamp and Henshaw, 1982, 1986, 1987a, b; Stamp, 1987; Szabados *et al.*, 1987; Mathews *et al.*, 1993; Raemakers *et al.*, 1993; Taylor and Henshaw, 1993; Konan *et al.*, 1994). Even though it is now possible, in principle, to regenerate cassava plants from a number of cultivars, the efficiency of regeneration achieved so far is low. In their best experience, Szabados *et al.* (1987) obtained an average of 1.15 plantlets

per primary explant. Stamp and Henshaw (1987a) studied the regeneration of somatic embryos derived from cotyledon explants and found that only 14% of the embryos that they started with eventually regenerated into plants.

Another strategy for plant regeneration is organogenesis. Cassava organogenesis is independent of callus formation and auxin treatment. Unlike most plants, there is no intermediary stage of callus production during organogenesis. Instead, shoot primordia are induced directly from cotyledons of somatic embryos and young leaf lobes on Murashige and Skoog (MS) (Murashige and Skoog, 1962) medium supplemented with 6-benzyladenine (BA) (Li *et al.*, 1996; Mussio *et al.*, 1998).

Regeneration of cassava has also been reported using meristem culture techniques (Kartha *et al.*, 1974; Bajaj, 1983). Meristem culture could provide an alternative means to generate explants for transformation studies, but it is difficult to obtain adequate numbers of meristems for transformation experiments. Apart from serving as explants for cassava transformation, meristem culture serves a more important role in providing disease-free plants, especially for plants infected with viruses as meristems are generally devoid of viruses. Meristems, therefore, serve as a means for viral decontamination as well as in multiplication of cassava.

The isolation and culture of cassava protoplasts have been performed (Mabanza and Jonard, 1983; Mabanza, 1984; Szabados *et al.*, 1987; Villegas *et al.*, 1988; Nzoghe, 1989). Prior to the report of Sofiari (1996), only one successful regeneration from protoplasts has been reported (Shahin and Shepard, 1980) but this has not been reproduced.

Currently, the most reliable method for cassava regeneration is through the young leaf lobes (and perhaps, through suspension cultures, which is more time consuming and requires more dexterity). Somatic embryos have been obtained from a number of cultivars, but there is still the need for optimization of the regeneration procedures. Results from the field tests of cassava plants derived from embryogenesis showed that somaclonal variation is not a problem in cassava. This makes plant regeneration via somatic embryogenesis a reliable tool for genetic improvement of cassava.

2.2 Transformation

Cassava transformation has been reported via *Agrobacterium*-mediated transformation (Li *et al.*, 1996; Arias-Garzon, 1997; Sarria *et al.*, 2000; Zhang *et al.*, 2000b; Siritunga and Sayre, 2003; Siritunga *et al.*, 2004) and by particle bombardment (Raemakers *et al.*, 1996; Schopke *et al.*, 1996; Zhang *et al.*, 2000a). *Agrobacterium*-mediated transformation is favored over particle bombardment because of the lower number of integrated sequences and greater stability of transformants. *Agrobacterium*-mediated transformation usually results in the transfer of 1–3 copy(ies) of the transgene to plants compared to the particle gun, which has been known to deliver up to 12 copies of a transgene. Importantly, the introduction of multiple transgene copies can lead to gene silencing (Alien *et al.*, 1993; Matzke and Matzke, 1995; Meyer and Saedler, 1996).

The first published attempt to transform cassava cells was that of Calderon (1988). He inoculated leaf pieces, stem pieces, and embryogenic callus with *Agrobacterium*-containing plasmids with the coding sequences for neomycin phosphotransferase II (*nptII*), phosphinotricin acetyltransferase (*bar*), or β -glucuronidase (*uidA*). He isolated callus lines expressing the phenotype expected from the transformation tissue.

Subsequent reports of transient gene expression followed (Franché *et al.*, 1991; Arias-Garzon and Sayre, 1993; Luong *et al.*, 1995). Arias-Garzon and Sayre (1993) observed a tissue-specific inhibition of transient gene expression in cassava associated with elevated DNase activity. Using a cauliflower mosaic virus (CaMV) 35S promoter, they observed several hundred localized regions that expressed β -glucuronidase activity in cassava leaves but virtually none in the roots. This shows that different parts of cassava plant respond differentially to transient transformation treatments. Luong *et al.* (1995) reported transient expression of the *uidA* gene in cassava tissues by electroporation. However, in 1996, two reports of stable cassava transformation came out simultaneously; one using *Agrobacterium*-mediated transformation (Li *et al.*, 1996) and the other microparticle bombardment (Schopke *et al.*, 1996).

The earliest reports of cassava transformation were only with marker genes of little agronomic importance (Li *et al.*, 1996; Schopke *et al.*, 1996). Additional reports of genetic transformation of cassava followed (Zhang *et al.*, 2000a, b). Sarria *et al.* (2000) reported the transformation of cassava with *bar* gene which confers resistance to the herbicide Basta. Transformed plants tolerated 200 mg l⁻¹ Basta, which proved toxic to the untransformed cassava plants.

In 2003, Siritunga and coworkers reported the transformation of cassava with the gene encoding HNL driven by the 35S promoter. HNL catalyzes the breakdown of acetone cyanohydrin, a product of linamarin hydrolysis, to acetone and cyanide (Siritunga *et al.*, 2004). This was an important development in cassava processing, because cassava roots contain little HNL (0–6%) relative to that in leaves. The rate of acetone cyanohydrin breakdown in the transformed plants was 41–75% faster than wild-type cassava (Siritunga *et al.*, 2004). These plants are advantageous for detoxification and processing of cassava food products especially for the poor people of the African continent who are perennially dependent on cassava for food.

2.2.1 Transformed cassava plants

There are more than 1500 cultivars of cassava worldwide (Alves, 2002). The high level of heterozygosity could be a function of cross-pollination in cassava resulting from the differences in timing of male and female flowers. The heterozygosity in cultivars is also reflected in its genetic transformability. Not all cassava cultivars are transformable to date. Only a few cultivars have been successfully transformed as furnished below:

- TMS 60444 (Schopke *et al.*, 1996; Gonzalez *et al.*, 1998; Zhang *et al.*, 2000a, b).
- TMS 71173 (Ihemere *et al.*, 2006).
- MCol 2215 (Arias-Garzon, 1997; White *et al.*, 1998; Siritunga and Sayre, 2003).
- MCol 122 (Zhang *et al.*, 2000a, b).
- MPer183 (Sarria *et al.*, 2000).

Regardless of the paucity of transformation success among cultivars, not all transformable

cassava cultivars respond to the available methods of transformation. Only TMS 60444 has been successfully transformed using particle bombardment of friable embryogenic callus (FEC) (Raemakers *et al.*, 1996; Gonzalez *et al.*, 1998; Zhang *et al.*, 2000a). Mcol 2215 (White *et al.*, 1998; Siritunga and Sayre, 2003; Siritunga *et al.*, 2004) and TMS 71173 (Ihemere *et al.*, 2006) are the most responsive to *Agrobacterium*-mediated transformation of cassava somatic embryo explants. Success with other cultivars is limited (Fregene and Puonti-Kaerlas, 2002).

2.2.2 Methods of cassava transformation

Cassava has been transformed using various types of tissues and explants as starting material including somatic embryo cotyledon (White *et al.*, 1998; Zhang *et al.*, 2000b; Siritunga and Sayre, 2003), young leaf lobes (White *et al.*, 1998), and FEC (Raemakers *et al.*, 1996; Gonzalez *et al.*, 1998; Zhang *et al.*, 2000a) (Table 1). Embryogenesis has been reported from FECs, somatic embryo cotyledons, and young leaf lobes. Direct organogenesis has been reported

Table 1 Methods used in cassava transformation^(a)

Target tissue	Regeneration mode	Gene transfer system	Selection	Transgenic tissue	Analysis	References

Scope for improvement	Yes	Yes	Yes
Marker use flexibility	3	3	3
Regeneration potential	2	4	5

^(a)Genotypes used: FEC (friable embryogenic calli)—TMS60444, Adera4, Mcol 1505, B. Rouge, Mtai5, R60 (Mtai 8), CM3306-4; Organo (organogenesis)—Mcol22, TMS60444, GSE—Mcol2215, MS71173, Mper183, Mcol22; plant regeneration: FEC—50% of the genotypes tested can be transformed; Organo—lower success on transformation of new varieties, GSE (germinating somatic embryo)—50% of the genotypes tested can be transformed

with somatic embryo cotyledons and young leaf lobes (Zhang *et al.*, 2000b). The efficiency of transformation of the different explants and methods was scored by scientists in the Advanced Cassava Transformation Group who met at CIAT in Palmira, Colombia (June 9–10, 2003). The somatic embryogenesis method using embryo cotyledons as explants was chosen to be the best method (Table 2) based on efficiency of regeneration, incidence of chimeras, speed of regeneration of transformed plants, and simplicity of transformation technique. The FEC system produced the largest numbers of transformants.

2.2.3 Gene promoters used in cassava transformation

Gene promoters are very important in the transformation process because they drive the tissue- and temporal-specific expression of genes. Without different promoters, controlled-gene expression is not possible. Some of the promoters used to date are listed in Table 3. Only a few of the promoters are root/tuber-specific, namely, Patatin and Potato GBSS.

The need for selectable markers in transformation arises from the need to distinguish between transformed and nontransformed tissues and plants. In cassava transformation, the selection of transformed tissues has been done using kanamycin and paromomycin (enabled by the *nptII* gene), hygromycin (enabled by *hpt* gene),

basta (enabled by *bar* gene), mannose (enabled by phosphomannose isomerase), phosphinotricin, and geneticin (see Table 2).

2.2.4 Problems with cassava transformation

Notwithstanding the successes recorded in cassava transformation, there are still many problems associated with cassava transformation. First and foremost, cassava has a low efficiency of transformation compared to other crops. The best recorded transformation efficiency for cassava is in the range of 3–5%. Most other crops have transformation efficiencies greater than 10% (Raemakers *et al.*, 1997). This makes it difficult to work with cassava. Added to the low efficiency of transformation is the difficulty to characterize transformed cassava plants molecularly. Southern blot analysis of cassava is very difficult. Part of the problem is that cassava genome is large. It has been reported that gene insertions from independently transformed cassava plants may have similar restriction patterns making it difficult to identify independent transformed lines (Siritunga, 2002).

Due to the low efficiency of cassava transformation, scientists working on cassava have come up with different tissues for cassava transformation. The most prolific regeneration system is the FEC, which has been reported to generate more transformed cassava (Raemakers *et al.*, 1996; Gonzalez *et al.*, 1998). However, the production

Table 3 Gene promoters that have been used in cassava transformation

Promoter	Source plant/organism	Size (kb)	Tissue specificity	References

of FECs requires that the cassava embryogenic tissues stay on high-auxin ($50 \mu\text{g l}^{-1}$) media for up to 6 months compared to the 1-month requirement for somatic embryogenesis. This long exposure to high auxin concentrations can lead to somaclonal variation in cassava.

2.2.5 Genetic manipulation of cyanogenesis in transgenic cassava

Daily consumption of cassava roots as a staple diet has been associated with the presence of chronic cyanide toxicity among the poor population in the tropics. The causative agents of cyanide toxicity are two cyanogenic glucosides, linamarin (95%), and lotaustralin (5%), which are present in all parts of the plant with the exception of seeds (Conn, 1979, 1994; Balagopalan *et al.*, 1988). Although various cultivars and hybrids of cassava are available, none has been found to be acyanogenic. Attempts to reduce cyanogens through conventional breeding have also not been successful. During the past 4 years transgenic strategies have been used to engineer acyanogenic cassava plants as well as plants in which the breakdown of cyanogenic glucosides and volatilization of cyanide is accelerated in the roots (Siritunga and Sayre, 2003, 2004; Siritunga *et al.*, 2004).

The starchy cortex of fresh cassava roots may contain between 15 and 1500 mg CN equivalents/kgfw depending on the cultivar and growth

conditions (O'Brien *et al.*, 1991). Cultivars having <100 mg CN equivalents/kgfw are designated as low-cyanide cultivars while cultivars having >500 mg CN equivalents/kgfw are known as high-cyanide cultivars. Interestingly, the outer peel (2–5 mm) of cassava roots has a high cyanogen content (average = 577 mg/kgfw) regardless of the cultivar and may serve to protect the root from herbivory (Bellotti and Riss, 1994). Leaf cyanogen content (average = 446 mg CN equivalents/kgfw) is also typically high regardless of the cultivar.

During the last 10 years the physiology and biochemistry of cyanogenesis in cassava has been elucidated (reviewed in McMahon *et al.*, 1995; Andersen *et al.*, 2000; Siritunga and Sayre, 2004). The major cyanogen in cassava is linamarin (95%), which is synthesized from valine (Figure 2). Two cytochrome P450s (CYP79D1 and CYP79D2) catalyze the first-dedicated step in linamarin synthesis. The end product of the cytochrome P450-catalyzed reactions is the hydroxynitrile intermediate, acetone cyanohydrin (Andersen *et al.*, 2000). Acetone cyanohydrin is subsequently glycosylated by a UDP-glucosyl transferase to yield the stable cyanogen, linamarin, which is stored in the vacuoles (see for review McMahon *et al.*, 1995).

Cyanogenesis in cassava is initiated by tissue disruption. Rupture of the plant cell vacuole releases linamarin, which is subsequently hydrolyzed by a cell wall or laticifer-localized β -glycosidase known as linamarase (Mkpong *et al.*,

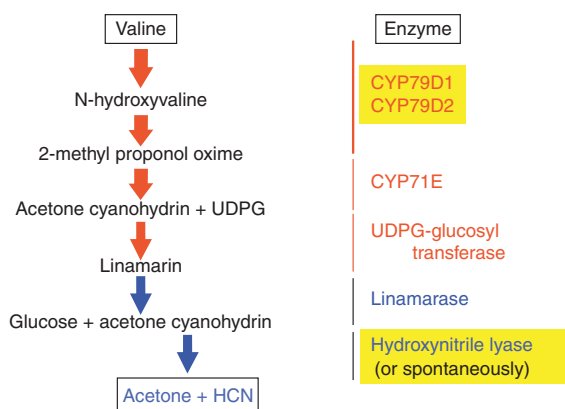

Figure 2 Linamarin synthesis and turnover pathway (high-lighted in yellow are the enzymes in the pathway that have been genetically manipulated to produce transgenic cassava with altered rates of cyanogen synthesis and breakdown)

1990; Hughes and Hughes, 1994). The products of linamarin hydrolysis are acetone cyanohydrin and glucose. Significantly, acetone cyanohydrin will spontaneously decompose to cyanide and acetone at pH >5.0 or temperature >35°C. Acetone cyanohydrin can also be broken down enzymatically by HNL. Cassava roots have much lower linamarase activities than leaves and very little or no HNL activity, presumably accounting for the accumulation of potentially toxic levels of acetone cyanohydrin in poorly processed cassava roots (White *et al.*, 1994, 1998).

Various human health disorders have been associated with the consumption of residual cyanogens from poorly processed cassava. Chronic exposure to low levels of cyanogens from poorly processed cassava has been associated with hyperthyroidism and neurological disorders including tropical ataxic neuropath (Mlingi *et al.*, 1992; Tylleskar *et al.*, 1992). In addition, the consumption of unprocessed, highly cyanogenic varieties of cassava may result in a permanent paralysis of the legs (*konzo*). The incidence of *konzo* is highest during crop failures or when less time is taken to process or remove cyanogens from cassava. Significantly, cyanide poisoning from poorly processed cassava is exacerbated by insufficient amounts of sulfur-containing amino acids (cysteine) in the diet (Tor-Agbidye *et al.*, 1999). Reduced sulfur or sulfur-containing amino acids are required for the detoxification of cyanide by the enzymes rhodanese and β -cyanoalanine

synthase. In the absence of sufficient cysteine, cyanide is converted to cyanate in the body. The brain is particularly sensitive to cyanate poisoning. The environmental conditions (e.g., drought and famine) that promote shortcut cassava-processing practices often go hand-in-hand with reduced availability of protein and/or cysteine in the diet.

In 2003 and 2004, Siritunga and Sayre reported the generation of transgenic cassava plants with reduced cyanogen potential in foods using two different strategies: (1) enhancement of HNL activity in roots to accelerate the turnover of cyanogens and cyanide volatilization during processing (Arias-Garzon and Sayre, 2000; Siritunga *et al.*, 2004) and (2) the inhibition of cyanogen production through suppression of *CYP79D1* and *CYP79D2* expression, the enzymes that catalyze the first-dedicated step in cyanogen synthesis (Figure 2) (Siritunga and Sayre, 2003, 2004).

Until recently, it had been assumed that the only cyanogen present in poorly processed cassava foods was linamarin. In 1992, however, Dr Hans Rossling and colleagues demonstrated that the major cyanogen present in poorly processed cassava roots was not linamarin but acetone cyanohydrin. In 1995, the Sayre lab characterized the distribution HNL in cassava roots, stems, and leaves (White and Sayre, 1995; White *et al.*, 1998). Their objective was to determine the biochemical basis for the unexpectedly high levels of acetone cyanohydrin in processed cassava food products. Significantly, they discovered that root HNL levels were <5% (protein basis) of those present in leaves. Thus, it was apparent that the low HNL activity in roots could contribute to the high acetone cyanohydrin levels present in poorly processed cassava roots. This observation led to the development of transgenic strategies to facilitate cyanogen elimination from processed cassava foods by overexpression of HNL in roots (Siritunga *et al.*, 2004).

Using an *Agrobacterium*-mediated transformation system, the Sayre lab introduced a cassava complementary DNA (cDNA)-encoding HNL driven by constitutive double CaMV 35S promoter into cassava. Transgenic cassava plants were verified by polymerase chain reaction (PCR) and Southern blot analysis for the integrated HNL cDNA (Siritunga *et al.*, 2004). The HNL activity of root extracts obtained from

Figure 3 Acetone cyanohydrin content of 8-month-old (greenhouse-grown) wild type and HNL overexpressing transgenic roots 2-h posthomogenization

in vitro transgenic plants ranged from 0 to 0.56 mM CN/mg protein/h. These HNL activities were as high as 13-fold greater than that for wild-type plants.

Analyses of acetone cyanohydrin levels in processed roots of HNL-overexpressing plants indicated that the rate of acetone cyanohydrin turnover was more than three times faster than for wild-type plants (Figure 3). It was also demonstrated that the turnover of acetone cyanohydrin was stoichiometrically equivalent to the loss of cyanide from the processed root tissues. The presence of elevated amounts of HNL enzyme in the transgenic roots resulted in accelerated turnover of acetone cyanohydrins compared to untransformed wild-type plants. Significantly, plants overexpressing HNL had normal root linamarin levels and linamarase activity indicating that the protective benefits of cyanogenesis or herbivore deterrence should not be compromised in the transgenic plants (Siritunga *et al.*, 2004).

In 2002, Dr. Birger Möller's lab identified the genes encoding the cytochrome P450s (*CYP79D1* and *CYP79D2*) that catalyze the first-dedicated step in linamarin synthesis (Andersen *et al.*, 2000). This discovery made it feasible to block linamarin synthesis by suppression of *CYP79D1* and *CYP79D2* expression in transgenic plants (Siritunga and Sayre, 2003, 2004). To determine the most effective strategy for reducing root linamarin content and to evaluate the role of linamarin transport in determining root linamarin levels, Siritunga and Sayre generated transgenic cassava in which the expression of the *CYP79D1*

and *CYP79D2* genes was selectively inhibited in leaves or roots only (Siritunga and Sayre, 2003, 2004). This selective down-regulation was achieved through the use of two different organ-specific gene promoters, *cab1* (leaf) and *patatin* (root), to drive the antisense expression of the *CYP79D1* and *CYP79D2* genes.

Reverse transcriptase-PCR analyses of five independent *cab1*-*CYP79D1/D2* antisense transformants constructs demonstrated a range of suppression of *CYP79D1* and *CYP79D2* transcript levels in leaves. Concomitant with this reduction was a reduction in leaf linamarin content (Figure 4a). *Cab1*-*CYP79D1/D2* transgenic plants had leaf linamarin levels ranging from 6% to 40% of wild-type levels. Surprisingly, Siritunga and Sayre (2003) observed a 99% reduction in root linamarin content in all *cab1*-*CYP79D1/D2* antisense transformants even though the root *CYP79D1* and *CYP79D2* transcript levels were unaffected (Figure 4a). They also demonstrated that *patatin*-*CYP79* antisense plants, having no detectable *CYP79D1* or *CYP79D2* message in roots, had wild-type root linamarin levels (Figure 4b) (Siritunga and Sayre, 2004). These results indicated that in 3–4-month-old cassava plants nearly all the linamarin present in roots was synthesized in the leaves and transported to the roots. Linamarin has previously been shown to be transported from seeds to growing shoots in germinating rubber tree seedlings as well (Selmar, 1993).

Surprisingly, when *cab1*-*CYP79D1/D2* antisense plants were transferred from *in vitro* conditions, where the media contained nitrate (40 mM) and reduced nitrogen (20 mM NH_4), to potting soil, they initially all died. When the *cab1*-*CYP79D1/D2* antisense plants were grown on MS media in which the ammonia was replaced with nitrate (60 mM) they failed to produce strong roots (Siritunga, 2002; Siritunga and Sayre, 2004). In contrast, *patatin*-*CYP79D1/D2* antisense plants grew normally when grown in modified MS media lacking ammonia or in potting soil. These results lead to a model for linamarin-derived nitrogen (CN) assimilation into amino acids by cassava roots (Figure 5). Siritunga and Sayre (2004) proposed that linamarin transported to the roots has two possible fates, (a) storage in the vacuole or (b) assimilation into amino acids. In the latter case, linamarin is deglycosylated, presumably by

Figure 4 Linamarin content of leaves and roots from control: (a) cab1-CYP79 and (b) patatin-CYP79 cassava transformants; the maximum linamarin content (100%) in leaves (■) and roots (■) of wild-type plants was 80 and 3.4 μ g/gdw, respectively (Based on Siritunga and Sayre, 2003, 2004)

a generalized β -glucosidase, generating cyanide. The cyanide is then assimilated along with cysteine via β -cyanoalanine synthase to produce β -cyanoalanine and sulfide. The β -cyanoalanine is then hydrated to form the amino acid asparagine. Deamination of asparagine generates aspartate and free ammonia, which can be reassimilated by the glutamine synthetase/glutamate synthase cycle (Lea *et al.*, 1990, 1992). Consistent with this model, Nartey (1969) has reported that germinating cassava seedlings exposed to 14 CN incorporated 49% of the radioactive label into the amide carbon of asparagine and 6% into aspartate. Furthermore, it has been reported that the activities of β -cyanoalanine synthase and β -cyanoalanine hydrazase are threefold greater in roots than in leaves (Elias *et al.*, 1997a, b). Quantitative real-time PCR has also demonstrated that transcripts of β -cyanoalanine synthase are equally abundant in the leaf and roots of cassava (Siritunga *et al.*, personal communication). At present, the relative linamarin flux between storage and amino acid metabolism remains unknown and is the focal point in future research. But there is compelling evidence in support of linamarin being transported from leaves to root and playing a substantive role in root nitrogen metabolism.

More recently, cab1-CYP79D1/D2 antisense plants having root cyanogen levels greater than 0.3% of the wild-type level been recovered after transplantation to soil. These results

suggest that a threshold root linamarin level is required for adequate root formation. Putative transgenic plants that have been engineered to express CYP79D1/D2 RNA-interference (RNAi) constructs driven by the CaMV 35S promoter have been shown to root successfully; however, there was no analysis of the level of CYP79D1/D2 expression in these putative transgenic plants (Jørgensen *et al.*, 2005). Overall, these results suggest that linamarin is synthesized in roots and serves in part as a transportable form of reduced nitrogen in addition to providing protection from herbivory.

Figure 5 Model for linamarin-derived nitrogen (CN) assimilation into amino acids by cassava roots

2.2.6 Transgenic approaches to controlling viral disease in cassava

Cassava mosaic disease (CMD) causes substantial losses in productivity potentially impacting food security in Africa. In 2002, yield losses attributed to CMD were estimated to be 20–28% of the total cassava production in Africa. CMD is caused by a bi-partite gemini virus (African cassava mosaic virus, ACMV) that is transmitted by white flies in Africa. Various strains of ACMV have been identified that vary in the severity of disease symptoms. Complicating matters is the observation that recombination between virulent strains can occur in coinfecting plants accelerating the generation of new and potentially more virulent strains. ACMV-tolerant cultivars have been identified and incorporated into breeding programs in Africa. Marker-assisted selection strategies are being used to map the resistance gene(s). The use of conventional breeding strategies to develop ACMV-resistant lines have been impaired, however, due to the high heterozygosity and inbreeding depression in many farmer-preferred cultivars. As a result, a number of transgenic strategies have been employed to suppress viral replication and transmission.

The first transgenic plants resistant to ACMV were reported in 2004 (Chellappan *et al.*, 2004a, b). Introduction of the *AC1* gene, encoding the Rep protein, which is required for viral replication, induced post-transcriptional silencing of the *AC1* gene via the generation of multiple small interfering RNAs targeted against the *AC1* transcript. In addition, full length AC1 protein was generated in the transgenic plants. Transgenic plants had substantially reduced symptoms compared to wild-type plants even after 2-month postinfection. No apparent role for AC1 protein expression in viral resistance was established. The AC1 transgenic plants were generated, however, by particle gun-mediated transformation, which resulted in the integration of multiple copies of transforming DNA. Subsequently, after several subclonings of the plants, it was observed that the viral resistance was lost. This was presumably due to gene silencing.

In 2005, Zhang and coworkers reported the development of transgenic cassava with enhanced resistance to ACMV using a targeted antisense approach. Small sense- and antisense-interfering

RNAs were generated against several viral RNA targets including the Rep (*AC1*), TrAP (*AC2*), and REn (*AC3*) transcripts, which are involved in viral replication and expression. The antisense constructs were fused to the 3' UTR (3' untranslated region) (prior to the terminator sequence) of the selectable marker gene used for selection of transgenic plants. Viral replication and disease symptoms were substantially reduced in transgenic leaves using moderate and high infection pressures.

2.2.7 Genetic manipulation of starch in transgenic cassava

One of the most important steps in starch biosynthesis is the conversion of triose phosphates into hexose phosphates, which are required for starch biosynthesis. Starch biosynthesis in roots takes place in heterotrophic plastids that lack fructose-1,6-bisphosphatase, an important enzyme for the interconversion of triose phosphates to hexose phosphates (Entwistle and ap Rees, 1990) (Figure 6). The precursor for starch biosynthesis, adenosine diphosphate (ADP)-glucose is not always made in the organelle of starch synthesis. The lack of fructose-1, 6-bisphosphatase in heterotrophic plastids necessitates the supply of substrates (ADP-glucose) for starch synthesis (Entwistle and ap Rees, 1990) from the cytoplasm. The enzyme catalyzing the first-dedicated and rate-limiting step in starch synthesis is ADP glucopyrophosphorylase (AGPase). In dicots AGPase is localized typically in the plastids but may also be present in the cytoplasm in some plant species (Denyer *et al.*, 1996). In cereals and tomato fruits, AGPase is cytoplasmic and ADP-glucose is transported into the plastid in exchange for adenosine monophosphate (AMP) by the adenylate translocator (Mohlmann *et al.*, 1997).

ADP-glucose pyrophosphorylase is a heterotrimeric enzyme that consists of a large subunit (shrunken2 locus, 54–60 kDa) and a small subunit (brittle2 locus, 51–55 kDa.). These subunits are also known as S and B subunits named after the loci from which the first AGPase cDNAs were cloned from maize (Bae *et al.*, 1990; Preiss *et al.*, 1990). The individual subunits each are catalytically active, however, optimal activity is observed in the heteroenzyme complex. In potato,

In 2006, Ihemere and coworkers reported the transformation of cassava using *Agrobacterium* harboring a *patatin-chloroplast transit sequence-glgC* transfer-DNA (T-DNA) cassette (Ihemere *et al.*, 2006). Transformed plants were confirmed by RT-PCR and Southern blot analysis. Tuber-specific expression of the *glgC* gene as confirmed by RT-PCR analysis (Ihemere *et al.*, 2006). AGPase assays demonstrated that the transgenic had 70% higher total AGPase activity than the wild type plants. The phosphate insensitive (bacterial) AGPase activity was 13-fold greater in transgenic than wild type plants reflecting expression of the phosphate-insensitive *glgC16* gene (Ihemere *et al.*, 2006).

Greenhouse-grown transgenic plants (3D-1 and 3D-3) expressing the highest AGPase activity had greater root fresh weight, greater root leaf numbers and greater top fresh weight per plant than wild type plants (Ihemere *et al.*, 2006). The roots' fresh weight yields of transgenic cassava plants were 2.7-fold greater than those of wild type roots. The transformed plants also had more roots per plant (8–12 roots/plant) than the wild type plants (average = 7 roots/plant). Root and shoot dry weight were also greater in transgenic versus wild-type plants, possibly reflecting a reduction in feed back inhibition on carbohydrate accumulation (Ihemere *et al.*, 2006). Interestingly, the observed increases in dry weight were not associated with an increase in starch density but with an increase in root size and number. These results suggest that the density of amyloplasts/cell in roots is not subject to substantial variation.

2.2.8 Starch modification

In 2005, Raemakers and colleagues reported the generation of amylose-free transgenic cassava by antisense inhibition of granule-bound starch synthase in cultivar TMS 60444. Amylose biosynthesis in cassava roots is catalyzed mainly by granule-bound starch synthase 1 (*gbss1*; Raemakers *et al.*, 2005). A reduction in the amylose synthesis could be achieved by down-regulating *gbss1*. The suppression of *gbss1* expression in other crops (potato, maize, wheat, and rice) resulted in the production of amylose-free starch (Visser and Jacobsen, 1993; Chakraborty *et al.*, 2004). Amylose-free

starch has desirable physico-chemical properties compared to amylose-containing starch. For example, amylose-free starch has a higher granule-melting temperature, less retrogradation, and better adhesive characteristics than amylose-containing starch (Visser *et al.*, 1997). The cassava amylose-free starch generated by Raemakers and coworkers has similar properties as the preceding amylose-free starch in potato, maize, wheat, and rice (Visser and Jacobsen, 1993; Chakraborty *et al.*, 2004) and is characterized by increased stability of the gel (Raemakers *et al.*, 2005). The starch particle size distribution for amylose-free and amylose-containing plants was similar. The authors also observed that the amylose-free starch had a higher melting temperature than the amylose-containing plants. The chain length distribution of the amylose-free and amylose-containing starches were the same, hence, the down-regulation of the *gbss* activity did not affect starch chain length. The other known modification of the cassava starch biosynthetic pathway was the antisense inhibition of the AGPase gene, which resulted in drastic reduction of starch and an increase in the amount of sugars in cassava roots (Munyikwa *et al.*, 1998). Starch biosynthesis in the AGPase antisense plants was limited to the root epidermal layer. This has no known industrial or agricultural applications save for the validation of the role of AGPase in starch biosynthesis.

3. FUTURE DIRECTIONS FOR PRECISION-ENGINEERED CASSAVA

In 2005, the Bill and Melinda Gates Foundation announced support for a major initiative to metabolically engineer cassava to provide complete nutrition for persons subsisting on a cassava-based diet. The BioCassava Plus Program (<http://biocassavaplus.org>) has eight objectives. These objectives include, elevating protein, iron, zinc, vitamin A and E levels to meet the minimum daily requirement in a 500 g cassava meal. In addition, cyanogenic glycoside levels will be reduced in cassava foods to safe or nontoxic levels, the shelf life of harvested roots will be extended from 2 days to several weeks, and CMV resistance will be engineered into cassava. Once each of these individual objectives has been achieved the traits will be stacked into local cultivars, field

tested, using approved biosafety systems, and used in human feeding trials to determine the bioavailability of the introduced nutrients. Field trials of transgenic cassava will be conducted in the targeted African countries of Nigeria and Kenya as the products develop. The long-term objectives are to provide precision engineered products that provide complete nutrition as well as value-added traits that facilitate income generation.

Recognizing the global importance of cassava, the DOE-Joint Genome Sequencing Program was announced in 2006, a cassava genome sequencing project. Complete coverage of the cassava genome is anticipated by 2008. In addition, the availability of full-length EST libraries and a cassava DNA chip are anticipated in the near future. These tools will facilitate discovery of potentially novel genes or gene regulatory networks that impart enhanced drought and pathogen tolerance, high photosynthetic capacity, and polyterpenoid production to cassava. These tools also will facilitate precision engineering strategies to alter the metabolism of cassava roots and shoots to facilitate crop biofortification and the development of cassava as a biofuel crop for the tropics.

1. INTRODUCTION

1.1 History, Origin, and Distribution

Cotton is the world's most important natural fiber. Cotton plant has played a significant role in the economy, social structure, and history of many countries around the globe. Despite the availability of synthetic alternatives, it continues to be an important source of fiber for the textile industry. The word "cotton" is derived from the Arabic word "*al qatan*" (Chaudhry and Guitchounts, 2003). Cotton has been cultivated and used to make fabrics for over 7000 years. It is speculated that cotton may have existed in Egypt as early as 12 000 BC and fragments of cotton fabrics have been found by archeologists in Pakistan (3000 BC), Mexico (from 3500 BC), India (3000 BC), Peru (2500 BC), and the southwestern United States (500 BC) (Stewart, 2001).

Cotton is adapted to warm climates and is cultivated from 45° North latitude to 32° South latitude. It is grown in approximately 80 countries worldwide by over 20 million farmers. Over 90% of the cotton is grown in the Northern hemisphere. Amongst the commercially cultivated species, over 90% of worldwide acreage is devoted to the tetraploid, *Gossypium hirsutum* ($2n = 4x = 52$) or upland cotton (Brubaker *et al.*, 1999). Another tetraploid, *Gossypium barbadense* or Egyptian

cotton is also grown in some parts of the world for its prized extra-long staple. The two Old World diploid species, *Gossypium arboreum* and *Gossypium herbaceum*, are still cultivated in some parts of Africa and Asia. However, these occupy a very small percentage of the total worldwide cotton acreage because of their low productivity and poor quality fiber. The global area of cotton cultivation in 2006 is estimated to be approximately 34.4 million hectares leading to total fiber production of 25 million metric tons. Interestingly, the world average cotton yield was 564 kg ha⁻¹ in 1995 compared to 726 kg ha⁻¹ in 2006. Much of the yield gains in the last decade are attributed to adoption of biotech cotton varieties (Cantrell, 2006).

1.2 Taxonomy and Botanical Distribution

Gossypium is a complex taxon comprised of over 50 perennial species that span the globe (Fryxell, 1992). Thus far, on the basis of cytogenetics and interspecific hybrid viability/fertility, eight diploid genomes designated A through G plus K have been recognized (Percival *et al.*, 1999). Some of the diploid cottons are poorly described and new *Gossypium* species continue to be discovered in some parts of the world. The original lineage of *Gossypium* may have arisen 10–20 million years

ago judging from the diverse spp. of *Gossypium* now growing wild in Australia, Africa, Arabia, and Mesoamerica (Brubaker *et al.*, 1999). At one point, in ancient Africa a line of the cotton genus denoted *Gossypium* evolved to produce trichomes (plant hairs) on the seed. These migrated to different parts of the world. One species found wild in Southern Africa is *G. herbaceum*. A species established and cultivated in Southern Asia is *G. arboreum*. The third diploid species (putatively identified as *Gossypium raimondii*) is no longer found in Asia or Africa, but is believed to have migrated to the Western Hemisphere (New World) approximately 1–2 million years ago (Brubaker *et al.*, 1999). All three of these species were diploid and had a basic chromosome number of $2n = 2x = 26$. About the time of migration of one of the diploid species to the New World, a critical hybrid event occurred between two of the species (similar to *G. herbaceum* and *G. raimondii*) (Wendel and Cronn, 2002). This polyploid hybrid retained the ability to produce fibers and was more vigorous than the diploid parental species. It became established and radiated out to different regions of the New World. Migration of the polyploid to diverse regions and subsequent isolation contributed to the origin of *G. hirsutum* in the Yucatan and *G. barbadense* in Peru. Other tetraploids diverged in Brazil (*Gossypium mustelinum*), Galapagos (*Gossypium darwinii*), and Hawaii (*Gossypium tomentosum*). All of these tetraploid species are perennial and adapted to short-day tropical environments. This means they flower when daylengths are less than 12 h. This prevents migration and adaptation to more temperate regions. The discovery of genetic variants in *G. hirsutum* and *G. barbadense* allowed these perennial species native to the tropics to be grown as an annual crop with good yields in temperate long-day environments. This is very similar to domestication events for day neutrality in tropical maize (*Zea mays* L.) and grain sorghum (*Sorghum bicolor* L. Moench). Hendrix and Stewart (2005) estimated the 2C nuclear DNA content of the AD tetraploid cotton ($2n = 4x = 52$) as being about 4.91 pg (picogram) or 2401 Mb (1C content). This is approximately additive for the putative A genome donor, *G. herbaceum* ssp. *africanum* and the D genome donor *G. raimondii*.

1.3 Economic Importance

Cotton is the single most important textile fiber in the world, accounting for nearly 40% of total world fiber production. The top three cotton producers, China, the United States, and India, together provide over half the world's cotton. The United States, while typically ranking second to China in production, is the leading exporter, accounting for over one-third of global trade in raw cotton. The US cotton industry accounts for more than \$25 billion in products and services annually, generating over 400 000 jobs in the industry sectors from farm to textile mill.

The cotton fiber is remarkable and unique in the plant kingdom. It is a modified plant hair or trichome that differentiates from epidermal cells of the seed coat. Typically, there are about 25–30 ovules that develop into cottonseed within the cotton boll (Kim and Triplett, 2001). Fiber is a single living cell that can grow extremely fast to achieve an average length of 25–35 mm or a 3000-fold increase during development (Stewart, 1975; Applequist *et al.*, 2001; Taliercio *et al.*, 2005). Approximately 25% of the epidermal cells elongate and differentiate into fibers giving rise to 14 000 to 18 000 fibers per seed (Bowman *et al.*, 2001); however, as many as 30 000 fiber cells per seed have been reported (Basra and Saha, 1999). The process of fiber development has been categorized into following four overlapping stages: initiation, elongation, secondary cell wall synthesis, and maturation (Basra and Malik, 1984). The cotton fiber takes from 40 to 60 days to develop completely. The mature cotton fiber has two clearly defined cell walls, a primary and secondary cell wall. The degree of secondary wall thickness determines the fineness of the fiber. Micronaire (fiber's resistance to airflow) is the measure of fiber's fineness. Cotton fiber represents one of the purest forms of crystalline cellulose. It is a polysaccharide polymer composed of 100–15 000 glucose molecules. When the cotton boll opens, the mature fibers dry into flat, twisted, ribbonlike structures that become interlocked. This interlocking permits spinning into fine, strong thread. Its crystalline and porous structure makes a fiber that is versatile, capable of binding dyes, very absorbent, and withstands repeated washing.

The properties of the cotton fiber determine its utility to the textile industry. Fortunately, the length, strength, and fineness of the cotton fiber are heritable traits amenable to careful breeding and selection (Benedict *et al.*, 1999). All of these traits can be measured analytically and are displayed prominently on all bales of cotton grown in the United States. The value of the bale to producer is determined by these fiber properties.

There are diverse and important uses of cotton products beyond textiles (Cantrell, 2005). In addition to the fiber, cotton plant also produces large quantities of seeds. In fact, the plants produce 1.65 kg of seeds for every kilogram of fiber. In the year 2005, approximately 40 million metric tons of cottonseed was produced worldwide (FAO). This makes cotton the third largest field crop in terms of edible oilseed tonnage in the world. Cottonseed is also a balanced source of fiber and protein. The whole cottonseed or the meal following oil extraction is important animal feed, primarily for dairy cattle. Oil is extracted from cottonseed kernels following separation from the hulls. The kernels are flaked and crushed for oil extraction and cottonseeds typically yield 16% crude oil. Cottonseed oil is a major edible oil found in many food products. It is viewed as “naturally hydrogenated” with a 2:1 ratio of polyunsaturated to saturated fatty acids. It is valued as stable frying oil, not requiring additional processing thus avoiding the formation of trans fatty acids. It is rich in tocopherols, which act as natural antioxidants and prolong shelf life and stability. Although a substantial portion of global output is used for human nutrition in the form of edible oil, as mentioned earlier, the meal and a significant amount of cottonseeds are simply used as feed for cattle. A better utilization of this abundant but underutilized resource can help in meeting the nutritional requirements of the growing global population in future.

Very short fibers, referred to as linters, comprise about 8% of the weight of fuzzy cottonseed. The linters provide an inexpensive source of cellulose that requires less processing than that derived from wood pulp. These are used in many nonwoven household and medical products. In addition, linters find important usage in food products, photographic film, and molded plastic products. These fibers are used in the manufacture of high-

grade bond paper and are a major component of many currencies. Cellulose from cotton linters is used widely as carriers in cosmetics and many foods. Even the cottonseed hulls that are removed from kernels prior to oil extraction serve an important use as roughage in the feed for livestock.

Thus, cotton plant is not just a source of fiber, it provides many byproducts with diverse applications. Although fiber will continue to be the primary target for biotechnology-mediated improvement, various cottonseed components can also be modified and improved through genetic engineering to better serve the needs of mankind.

1.4 Traditional Breeding

Increasing profit per cotton field has been the ultimate objective for cotton plant breeders. Several strategies have been employed to meet this goal including improving host plant resistance, abiotic stress tolerance, fiber and seed qualities, and agronomic adaptability.

1.4.1 Breeding objectives

Breeding objectives are usually defined by the economic importance of the trait, availability of sources for improvement, and viability of incorporating targeted improvement into a high-yielding cotton variety.

1.4.1.1 Host plant resistance

Several insect, nematode, and disease maladies afflict cotton. Perhaps none are as notorious as the boll weevil (*Anthonomus grandis*) invasion of the US cotton belt, which financially ruined much of the cotton industry, created a societal upheaval and prompted scientists to begin searching for host plant resistance (HPR) to the pest (Jones, 2006). While no germplasm provided substantial resistance, early maturing varieties were developed that would provide temporal resistance or escape from the boll weevil (Walker, 1979). By developing cotton varieties that could produce a greater portion of their fruit early in the growing season before the second and third generations

of postdiapause boll weevils could reproduce, an economically acceptable cotton crop could be produced in many areas of the US cotton belt.

In the 1960s efforts to identify other mechanisms of resistance to different insect pests began to be sought. Several biochemical and morphological traits associated with cotton HPR have been identified with varying degrees of usefulness (El-Zik and Thaxton, 1989). Butler and Henneberry (1984) determined that fewer leaf trichomes resulted in greater cotton HPR to the whitefly, *Bemisia tabaci*. Increased tannins (Lege *et al.*, 1992) and gossypol (Bottger and Patana, 1966) as well as glabrousness (Lukefahr *et al.*, 1971) and nectariless (Butler *et al.*, 1972) traits have all been found to reduce *Heliothis* damage. Schuster *et al.* (1976) reported that plants lacking floral nectaries also were found to be less attractive to plant bugs (*Lygus hesperus*). The okra leaf trait confers resistance to pink bollworms (*Pectinophora gossypiella*) (Wilson *et al.*, 1986), and it proved to be a valuable means of improving pesticide penetration into the lower cotton canopy, which improves chemical pesticide efficacy.

Considerable breeding efforts have been directed toward improving nematode and disease resistance of cotton germplasm. Shepherd (1979) outlined methodology for screening germplasm for resistance to root-knot nematodes (RKNs) (*Meloidogyne incognita*) as well as developing several sources of resistant lines. Improving resistance to *Verticillium* wilt has been a major goal of several breeding programs throughout the world (Bell, 1992). To screen early-generation breeding lines for *Verticillium* disease resistance, breeders often establish fields with high fungal density that ensure plants are challenged by the pathogen. Occasionally breeders are capable of developing HPR to poorly defined diseases. In 1994, a new and devastating disease, bronze wilt, afflicted hundreds of thousands of US acres. Although Koch's postulate was never successfully completed with the disease, most breeders realized a strong relationship between cotton varieties, their pedigrees, and disease incidence. Consequently, breeders purged much of their material that was susceptible to bronze wilt. Since then, no major outbreak of the disease has been reported. In other situations, the disease has been very well defined but the economic effect is minimal. Such is the case with bacterial blight

(*Xanthomonas campestris*) (Chakrabarty *et al.*, 1997). Only minor commercial breeding efforts are made toward improving resistance because of limited and sporadic economic consequences of the disease (Blasingame, 2005).

1.4.1.2 Abiotic stress

Soil-moisture deficits generally are the most yield-limiting stress factor for cotton and can dramatically impact stability of performance. In certain growing areas, other abiotic stresses are of major concern such as excessive salt, heat and cold temperatures. Traditionally, abiotic stress screening entailed subjecting early-generation families and populations to extreme drought, heat, or cold conditions; then selecting the most productive plants to advance in breeding programs. Recently, more sophisticated methods of screening seedlings for drought tolerance were developed by Longenberger *et al.* (2006).

Heat tolerance usually is identified in plants by fertility ratings or pollen production in flowers. Programs approach screening for heat tolerance with different strategies. Some breeders emphasize early-generation screening to identify tolerance or sensitivity to extreme heat either under artificial heat or nurseries in specific areas where high temperatures are expected such as Arizona. Other breeders will wait and characterize heat tolerance of only advanced generation material that has undergone multiyear testing. Cool temperature stress typically receives very little attention during seedling stages of development and high levels of tolerance are often associated with larger seed size, and higher tolerance to seedling disease complexes.

For salt tolerance, usually minor efforts are made for selection and improvement. Gossett *et al.* (1994) indicated differences between New Mexico State University's Acala varieties and varieties developed in the mid-south, which suggest serendipitous enhancements due to the breeding program location.

1.4.1.3 Fiber quality

Because cotton's ultimate value is as a fiber crop, much attention has been given to improving fiber traits. By the early 1960s efforts were underway to

change the way cotton fiber quality was measured with high-volume instrument (HVI) testing. With this advent, breeders could then affordably evaluate fiber from individual plants and breeding lines and assign absolute and objective numbers to fiber properties. This technological innovation helped make rapid improvements in fiber traits.

Concomitant with HVI development, new techniques were being developed to break negative linkages among fiber properties and yield (Miller and Rawlings, 1967; Meredith and Bridge, 1971; Culp and Harrell, 1973). Fiber length and strength typically were characteristics most often targeted for improvement because of their importance to spinning quality, quantification by HVI, and existence of genetic improvement sources.

Today, many breeders employ very sophisticated crossing schemes designed to break linkages between yield and fiber qualities. Other fiber properties such as micronaire, elongation, length uniformity, fineness, and maturity also garner attention by breeders. Moreover, fiber properties in most lines are evaluated in several generations during the variety development process.

1.4.1.4 Seed quality

Because cottonseed represents only about 10% of the crop's economic value, minor breeding attention has been given to improving seed qualities. Seed size has typically been a trait receiving the most attention by breeders because small seed size can be associated with poor seedling vigor (Quisenberry and Gipson, 1974), but more importantly can cause problems at the gin by increasing seed coat fragments and neps (Barger and Garner, 1991). Cotton breeders monitor seed size through a seed index, which is the weight of 100-fuzzy seed. Unfortunately, smaller seed size is often associated with a greater lint-to-seed ratio, which is an important yield component.

A major devaluating characteristic of cottonseed is the presence of gossypol, a toxic secondary metabolite. Gossypol prevents nonruminants from consuming cottonseed and limits mature ruminant animals to safely consume only about 3 kg/day. In addition, gossypol makes oil extraction and utilization more expensive and less competitive against other oil crops such as soybeans (*Glycine max*) and canola (*Brassica napus*). The first

cotton variety with glandless seed was described by McMichael (1959). Less than two decades later several commercial glandless varieties were available (Hallowin *et al.*, 1978), but none of these lines were very successful because of the susceptibility of the plants to pests and lack of commercial value to growers.

1.4.1.5 Agronomic adaptation

Earliness of crop maturity can enhance yield and also reduce risk by avoiding late-season pests and aberrant weather. Early-maturing varieties are necessary for the northern areas of the cotton belt where heat units limit production. Early-maturing varieties also enable growers to more easily manage counter-season crop rotations such as winter wheat. Conversely, late-maturing varieties can improve drought tolerance (Dumka *et al.*, 2004). In latitudes closer to the equator, late-maturing varieties can exploit more heat units from the growing season, recover from fruit shedding, and translate that opportunity into greater yield potential than more determinant fruiting varieties.

The ideal boll type depends on location. On the high plains of Texas and Oklahoma where strong wind storms frequently occur, a tight storm-proof boll is preferred. However, the need for such a boll has decreased with the adoption of chemical harvest aids, which shorten the exposure time from defoliation until harvest. In the mid-south and southeast US, a looser boll, which is less prone to hard locking, is preferred. Bolls in this area need to be easily pulled out of the burr by mechanical pickers. Moreover, bolls need to open easily in the presence of low sunlight and high humidity, which are common in these regions during the harvest season.

1.4.2 Tools and strategies

A yield plateau was thought to have been reached in recent years due to several factors. Chief among these factors was a lack of genetic diversity caused in large part to, as Meredith (2002) suggested, breeding efforts directed toward added value traits. Genetic diversity is an important component for advancing breeding populations of cotton germplasm. Commercial level plant breeders

are pressed to quickly release high-performance varieties. Consequently, private breeders tend to use more in-house elite germplasm with a narrow genetic base in comparison to public cotton breeders (Bowman, 2000).

Most cotton breeders use a pedigree method of breeding, first described by Newman (1912), or slight derivation thereof. After initial hybridization, counter-season nurseries, especially for first filial plant generations, are frequently used to hasten development. Individual plants are selected in second filial or later generations after additive effects can be expressed. Many breeders use shuttle-breeding strategies to select in multiple environments such as a dryland nursery, a *Verticillium* wilt nursery, and an early-planted nursery. Initial testing of selected lines is done in high-yielding, well-controlled environments where the maximum amount of genetic yield and fiber potential can be expressed. As testing continues on advanced generations, trials tend to include more diverse growing environments to determine performance stability. The entire process generally takes at least 10 years from the initial cross-pollination to a finished cotton variety.

1.4.3 Achievements

In the year 1900, average cotton fiber yield per hectare was 218 kg in the United States (Ware, 1951); by 2005, it was 931 kg ha⁻¹ (Meyer *et al.*, 2006). While not all the gain can be attributed to genetic improvement, certainly cotton breeding programs deserve much credit. Meredith and Wells (1989) reported that in comparing modern cultivars versus antiquated cultivars, newer germplasm is capable of higher yields because of greater partitioning of dry matter to reproductive structures away from vegetation. Fiber quality is more heritable than yield potential and can affect crop quality even in the most environmentally diverse and challenging conditions (Krieg, 2002). Fiber quality has improved dramatically in almost all production regions. The most significant improvements have come in longer and stronger fibers.

Individual cotton breeding programs have made substantial contributions and developed reputations as centers of expertise in many areas of research and development. Public and private

breeding efforts in California made great strides in improving fiber quality and *Verticillium* and *Fusarium* wilt tolerance. Programs in Arizona are noted for improving fiber characteristics as well as heat and drought tolerance. The breeding program at New Mexico State University has developed Acala varieties that are well regarded for fiber quality and *Verticillium* wilt tolerance (Zhang *et al.*, 2005). The Texas A&M University breeding program in Lubbock released several lines with enhanced fiber qualities and *Verticillium* wilt tolerance. In College Station, TX, Texas A&M University breeding programs developed several germplasm lines and varieties with high levels of HPR to a wide array of maladies. Mid-south breeders have developed numerous lines that are highly adapted to a wide range of environments around the world. They also are noted for releasing germplasm and varieties with RKN resistance (Jenkins *et al.*, 1993). In the southeast, varieties, particularly from the USDA-Pee Dee program are well regarded for fiber properties. Internationally, breeders from Australia's Commonwealth of Scientific and Industrial Research Organization (CSIRO) program are responsible for releasing high-yielding, high-fiber quality varieties that are well adapted and widely grown throughout the world.

1.5 Limitations of Conventional Breeding, Rationale for Transgenic Breeding, and the First Generation of Engineered Cotton

Conventional cotton breeding can be a slow and methodical process with typical incremental improvements. Nontransgenic varieties have marginal retail value in comparison to other conventional cotton crop inputs. In contrast, transgenic cotton breeding increases the speed of developing high-valued cotton varieties with highly efficacious traits. Moreover, transgenic breeding not only offers better genes for specific traits, it also allows a faster, more convenient method of identifying these genes during the variety development process without the cumbersome negative linkages encountered during conventional breeding procedures. Use of polymerase chain reaction (PCR) technology and lateral flow strips allows breeders to identify target plants at the seedling stage or in environments where

screening is not possible. This greatly reduces the cost of nurseries and fallible phenotypic screening procedures.

Finding naturally altered and beneficial metabolic pathways that enhance abiotic stress tolerance is also virtually impossible due to screening inadequacies of large numbers of cotton genomes. With transgenic technology, pathways that can enhance stress tolerance can be altered, verified, and reliably reproduced in breeding programs.

The cotton plant is particularly susceptible to a wide variety of insect pests and nematodes. This vulnerability and the fact that cotton is generally not considered a food crop, production of cotton has traditionally relied on the use of large amounts of toxic pesticides. Prior to the introduction of Bt cottons, 5–10 insecticide applications were needed per season to control damage from insects (Benedict and Altman, 2001). Some estimates suggest that prior to the widespread adoption of GM (genetically modified)-cotton, nearly 25% of all insecticides used around the world were for production of cotton (Pannetier *et al.*, 1997; Gomez-Barbero and Rodriguez-Cerezo, 2006). Three classes of synthetic organic compounds including organophosphates, carbamates, and pyrethroids are used to control insect pests of cotton. These chemicals are expensive and harmful to people, wildlife, and the environment (Benedict and Altman, 2001).

With the exception of a few developed countries, cotton is mostly grown in developing countries as a cash crop by the resource-poor farmers. In some cases, their crops are destroyed by insects as some farmers cannot afford to buy the pesticides. In most cases, they resort to the use of some highly toxic chemicals leading to pesticide poisonings and deaths as they can rarely afford the proper equipment for safe chemical application (Mancini *et al.*, 2005).

The issues discussed above made cotton an ideal crop that could greatly benefit from genetic engineering. It was therefore, no surprise that upon receiving approval for commercial planting, of all the GM crops, cotton garnered the largest acreage for the first year in the United States (James, 1997). The GM cotton introduced in the United States was in the form of insect-resistant cotton (Bollgard® cotton; Jones *et al.*, 1996; Hardee and Herzog, 1997; Benedict and Altman, 2001;

Perlak *et al.*, 2001), herbicide (Buctril®)-resistant cotton (BXN57; Panter *et al.*, 1996), and herbicide (glyphosate)-resistant cotton (Roundup Ready® cotton; James and Krattiger, 1996). The gene-for-gene relationship demonstrated by Flor (1946) is an important concept in defending HPR traits against resistant pest populations. Pyramiding or stacking of genes, which offer different modes of resistance to the same pest, is much more feasible with transgenic technology. For instance, Monsanto now offers Bollgard II® technology and Dow offers WideStrike™ technology where each contains two independent genes responsible for cotton plants producing *Bacillus thuringiensis* (Bt) toxins to resist worms. This strategy decreases the likelihood of Lepidopteran insects developing resistance to both host plant gene products. The herbicide resistance traits mentioned earlier were the result of screening bacterial genomes for resistance. Resistant genotypes were then used as sources of tolerance in cotton plants. Thus, a vital component to ecologically and economically superior weed control was developed through transgenic breeding. Screening billions of cotton genomes for natural herbicide resistance would have been logistically impossible.

Cotton growers have adopted biotechnology at a faster pace than growers of any other crop. Ten countries, representing over 60% of the global area of cotton production, currently allow biotech cotton to be grown: Argentina, Australia, Brazil, China (Mainland), Colombia, India, Indonesia, Mexico, South Africa, and United States. In 2005/2006 crop season, it is estimated that 28% of the global area of cotton production was planted to varieties containing biotech traits, such as insect and/or herbicide resistance. This constitutes about 37% of total bales produced globally and about 38% of all exported bales. In the year 2004, GM cotton garnered 80% of US-, 66% of Chinese-, 80% of Australian-, and 85% of South African-cotton acreage (James, 2004). Often, cotton is the first crop to receive approval for commercial planting in many countries from their respective regulatory agencies. Biotech varieties are expected to account for 36% of 34.4 million hectares planted for cotton in 2006/2007 (Cantrell, 2006). GM varieties are projected to continue gaining their share of global cotton acreage. This bodes well for future products that are likely to be generated by further genetic modification of cotton.

2. DEVELOPMENT OF TRANSGENIC COTTONS

Several excellent reviews on transgenic cotton have been published in the last 15 years (Murray *et al.*, 1993; John, 1997; Paterson and Smith, 1999; Chlan *et al.*, 2000; Wilkins *et al.*, 2000; Rajasekaran *et al.*, 2001; Kumria *et al.*, 2003). In this chapter, we provide a comprehensive list of papers reporting genetic modification of cotton (Table 1). It includes reports published in international journals on the transformation of cotton using *Agrobacterium*, gene gun, or other alternative methods. Publications related to the intellectual property are sometimes overlooked in reviews, however, these provide additional and important new information not easily gleaned from traditional literature. Such information is essential in this age of rapidly advancing and increasingly complex biotechnology field. Therefore, a detailed list and discussion related to the relevant patents on cotton transformation methods, genes, promoters, and plants with engineered traits have been presented in this section. In addition, important issues concerning genetic engineering of cotton have also been highlighted. Production of transgenic cotton, especially via *Agrobacterium*-mediated transfer-DNA (T-DNA) delivery and somatic embryogenesis-mediated recovery of transformants, has become routine in some laboratories around the world. However, the fact remains that many laboratories, especially in the developing countries, continue to struggle with cotton transformation. This is because somatic embryogenesis in cotton is highly genotype-dependent and even with regenerable genotypes, the process is long, tedious, and requires a high level of tissue culture skills. Therefore, the laboratories that lack the necessary skills and resources are tempted to try alternative methods when embarking on projects involving cotton transformation. The results from many of these attempts have been questionable at best. We have addressed the issue of “cotton transformation methods” squarely, provided the necessary information to be able to identify the “real” transgenic events, and our hope is that investigators attempting cotton transformation for the first time will be able to make an informed choice.

2.1 Transformation Methods

2.1.1 *Agrobacterium*- or gene gun-mediated transformation of cotton cells followed by recovery of transgenic plants via somatic embryogenesis

The first two reports on successful transformation of cotton by *Agrobacterium*-method appeared as early as 1987 (Firoozabady *et al.*, 1987; Umbeck *et al.*, 1987). This feat was achieved only four years following the transformation of the model plant species—tobacco. However, the progress in producing transgenic cotton, especially in the academic laboratories, had been rather slow until the turn of this century. Although surprising considering the economic importance of cotton, the reasons for this dearth of reports on cotton transformation were the difficulties involved in producing transgenic cotton plants. A thorough investigation into various steps involved in generating transgenic cotton was conducted in the laboratory of K. Rathore at Texas A&M University and a comprehensive report unraveling the mystic surrounding cotton transformation was published in 2001 (Sunilkumar and Rathore, 2001). By using green fluorescent protein (*GFP*) as a reporter gene, this study revealed that the *Agrobacterium*-mediated transfer of T-DNA to the cotyledonary cells of cotton was a highly efficient process. In addition, the conversion of transient transformation events to stable events in cotyledon, hypocotyls, and petiole segments is quite efficient in cotton (Sunilkumar and Rathore, 2001; Rathore *et al.*, 2006). The difficulties in generating transgenic cotton are largely due to poor regeneration from cultured tissues. Recovery of transformed plants from cultured cotyledon-, hypocotyl- and petiole-derived callus tissues requires a careful selection of the friable, embryogenic callus, and several subcultures on various media under appropriate environmental conditions. Given the complexities of creating transgenic cotton, a simple yet robust method for cotton transformation was developed and has been described in detail (Rathore *et al.*, 2006). By following this protocol, it is possible to generate transformed cotton plants (cv. Coker 312) in 8–10 months. It should be noted,

Table 1 Summary of studies on transgenic cotton

Transformation method	Cultivar	Target tissue/mode of transformant recovery	Transgenes	Comments	Reference
<i>Agrobacterium</i>	Coker 310, 312, and 5110	H/somatic embryogenesis ^(c)	<i>cat</i> and <i>npII</i>	Enzyme assays and Southern for confirmation	Umbeck <i>et al.</i> , 1987
<i>Agrobacterium</i>	Coker 201	C/somatic embryogenesis ^(a)	<i>npII</i> and OCS	Immunoblot and Southern for confirmation	Firoozabady <i>et al.</i> , 1987
Gene gun	Coker 310	ESC/somatic embryogenesis ^(b)	<i>hpt</i>	Southern for confirmation	Finer and Mc-Mullen, 1990
<i>Agrobacterium</i>	Coker 312	H/somatic embryogenesis ^(c)	<i>CryIAC</i> , <i>CryIAb</i> , and <i>npIII</i>	Western and bioassay for confirmation	Perlak <i>et al.</i> , 1990
<i>Agrobacterium</i>	Siokra 1-3	H/somatic embryogenesis ^(c)	<i>npII</i> and <i>gusA</i>	NPTII and GUS enzyme assays for confirmation	Cousins <i>et al.</i> , 1991
<i>Agrobacterium</i>	Coker 312	H/somatic embryogenesis ^(c)	<i>npII</i> and <i>tfidA</i>	2,4-D monooxygenase activity, PCR, and 2,4-D resistance for confirmation	Bayley <i>et al.</i> , 1992
<i>Agrobacterium</i>	Coker 315	C/somatic embryogenesis ^(a)	<i>npII</i> , <i>gusA</i> , and <i>tfidA</i>	Southern, GUS enzyme assay and 2,4-D resistance for confirmation	Lyon <i>et al.</i> , 1993
Gene gun	Delta Pine 50, Delta Pine 90, Sea Island, Pima S-6	SAM from mature seed/shoot regeneration in culture ^(c)	<i>gusA</i>	GUS histochemical analysis and Southern for confirmation	McCabe and Martinell, 1993
<i>Agrobacterium</i>	Coker 312	C/somatic embryogenesis ^(a)	<i>npIII</i> , protease inhibitors	Western for confirmation	Thomas <i>et al.</i> , 1995
Gene gun	Not stated	SAM from mature seed/shoot regeneration in culture ^(c)	<i>npIII</i>	Western for confirmation against insects	Chlan <i>et al.</i> , 1995
Gene gun	Delta Pine 50	SAM from mature seed/shoot regeneration in culture ^(c)	Fiber-specific E6 antisense and <i>gusA</i>	GUS assay, Northern, Western, and fiber quality analysis for confirmation	John, 1996
Gene gun	Coker 312, Delta Pine 50, Sea Island	SAM from mature seed/shoot regeneration in culture ^(c)	Fiber-specific, FbL2A promoter driving <i>phaB</i> and <i>phaC</i> , and <i>gusA</i>	GUS assay, Southern, Western, and biochemical analyses for confirmation	Rinehart <i>et al.</i> , 1996
Gene gun	Delta Pine 50	SAM from mature seed/shoot regeneration in culture ^(c)	Fiber-specific, E6 or FbL2A promoter driving <i>phaB</i> and <i>phaC</i> , and <i>gusA</i>	GUS assay, Southern, Northern, microscopic, and biochemical analyses for confirmation; fiber's thermal properties were altered	John and Keller, 1996; Chowdhury and John, 1998
<i>Agrobacterium</i> and gene gun	Coker 315 and Acala varieties	C, H, ESC/somatic embryogenesis ^{(a)(b)(c)}	<i>npIII</i> , mutant native AHAS genes	Southern and resistance to herbicides, imidazolinone and sulfonylurea, for confirmation	Rajasekaran <i>et al.</i> , 1996

however, that regeneration of cotton plants from cultured tissue via somatic embryogenesis still remains highly genotype dependent (Trolinder and Xhixian, 1989). Information presented in Table 1 suggests that transformation of cells within hypocotyl or cotyledon segments via *Agrobacterium* method, selection and proliferation of transformed cells in culture, followed by somatic embryogenesis appears to be the most popular means of creating transgenic cotton. This seems to be the method of choice even in industrial laboratories. Some investigators have successfully utilized microprojectile bombardment (gene gun or biolistics) or *Agrobacterium* to transform embryogenic suspension cells and then recovered the transformed cotton plants via somatic embryogenesis (Finer and McMullen, 1990; Rajasekaran *et al.*, 1996).

2.1.2 Transformation of cells within the shoot apices to generate transgenic cotton plants

As described earlier, plant recovery systems based on somatic embryogenesis from cultured tissues are time and resource intensive and highly genotype dependent. It is precisely these difficulties with regeneration that have led many researchers to seek alternative procedures for the recovery of transgenic cotton plants following transformation. Some studies have reported direct transformation of cells in the shoot apical meristem, either via the gene gun or *Agrobacterium* method. Since plants can be recovered from these tissues fairly easily (Gould *et al.*, 1991), it was hoped that this system would make transformation of cotton more genotype independent. Particle bombardment studies have provided concrete evidence showing that this method can transform either epidermal cells of the L1 layer or the germline progenitor cells in the L2 or L3 layer (McCabe and Martinell, 1993; McCabe *et al.*, 1998). The progeny from L1 transformants did not inherit the transgene, while the germline transformants (recovered from transformation of L2/L3 cells) were able to pass on the transgenic trait to subsequent generations. These studies also suggest that the primary transformants recovered from these shoot apices are chimeric and the efficiencies of germline transformations are extremely low.

Three different laboratories have reported production of transgenic cotton plants via *Agrobacterium*-mediated transformation of the shoot apex (Zapata *et al.*, 1999; Satyavathi *et al.*, 2002; Yuceer and Koc, 2006). These reports have provided results from PCR and Southern analyses that suggest integration of transgenes. Transformation efficiencies as high as 60–70% were reported for three different cotton cultivars in the study conducted by Satyavathi *et al.* (2002). These rates would be considered high for any species, especially cotton. It should be noted that transformation efficiencies were based on the resistance of shoot tip explants to kanamycin, a highly unreliable measure of transformation in cotton. When shoot tip explants are used as the target tissues, the recovery of heritable transgenic events is expected to be due to the transformation of cells in the L2 or L3 layer of the shoot apical meristem. However, the ability of the shoot tip to survive kanamycin medium, as the sole criterion for transformation, can be misleading. This is because *Agrobacterium* can easily transform the cells within the wounded base of the shoot apex. In this situation, the shoot tip explant will be able to survive when cultured on kanamycin medium because of the protection conferred by the transformed cells within the wounded site at the base (unpublished results from K. Rathore's Laboratory). In addition, contaminating *Agrobacterium* cells can contribute to incorrect interpretation of the results from Southern analysis unless it is performed with proper controls and the use of an appropriate restriction enzyme. *Agrobacteria* are not always eliminated with antibiotic treatment, can persist in tissues following transformation, and are sometimes found even in the regenerated plants (Matzk *et al.*, 1996; Barrett *et al.*, 1997). None of the studies, involving *Agrobacterium*-mediated transformation of shoot apices, investigated the type of cells that were being transformed in the apical meristem. This is an important issue because the transformation of meristematic cells in the shoot apex remains controversial (Potrykus, 1991). As mentioned previously, gene gun studies conducted by scientists at Agracetus have shown that when the cells within the shoot apex are transformed, the resultant plant following regeneration is chimeric (McCabe and Martinell, 1993; McCabe *et al.*, 1998). By careful tracking of

the transgenic leaves and by selective pruning of nontransgenic branches, they were able to obtain a uniformly transformed mericlinal plant. The same principles should apply when *Agrobacterium* is used for transformation of cells in the shoot apex. Even if *Agrobacterium* is somehow able to transform deeper cells within the L2 or L3 layers of the shoot meristem, a chimeric plant will be produced. Without precise pruning of such a plant to eliminate nontransgenic branches, it will not be possible to obtain T₁ seeds that segregate in a Mendelian manner. Thus, it is important to identify the cell types within the shoot apex that are transformed by the *Agrobacterium* (*GFP* will make an excellent reporter gene here) and provide a clear-cut proof of integrative transformation. Addressing these critical aspects of the transformation process will ensure widespread adoption of the method because recovery of a normal, fertile plant from a shoot apex is relatively easy and genotype independent.

2.1.3 Alternative methods used to transform cotton

Regeneration of transformants is often the limiting step in the creation of transformed plants in any species and it is especially true in the case of cotton. Therefore, attempts have been made to completely bypass the *in vitro* regeneration process to produce transgenic cotton by introducing the transgene(s) into pollen/pollen tube. Gounaris *et al.* (2005) reported production of transformed cotton by using pollen that had undergone microprojectile bombardment to introduce the transgene. Results from PCR analysis were presented as proof of transformation. Without additional molecular and genetic proofs and some data on the transformation efficiency, it is difficult to assess the effectiveness of this method for cotton transformation. Li *et al.* (2004) described a method that involved direct co-cultivation of pollen grains of brown cotton with *Agrobacterium* under vacuum and then pollination of emasculated flowers with the pollen/*Agrobacterium* mixture. Seeds obtained from plants pollinated in this manner were screened on antibiotic medium to select transformants. However, given the fact that pollen from most commercial varieties of

cotton is extremely susceptible to bursting in an aqueous environment, the general applicability of this method remains questionable. Wang *et al.* (2004b) described a rather simplistic approach that required direct application of naked plasmid bearing the transgene to the stigmatic surface. Seeds obtained from the treated flowers were germinated on a medium containing the herbicide, BastaTM for the identification of transformants. Although the technique described is extremely simple and does not require a biological vector such as the *Agrobacterium*, it is difficult to envision how the transgenes are delivered into the target cells without application of any physical or chemical treatments. The nature of the target cell(s) is also unclear in this system. Without a clear understanding of the transfer mechanism and solid proof of integrative transformation, it is difficult to assess the suitability of these alternative methods for performing cotton transformations in a routine manner.

2.2 Regeneration of Cotton Plants from Transformed Cells

An important aspect of genetic engineering is efficient recovery of whole plants from the cells that have undergone stable transformation following the introduction of a transgene by physical, chemical, or biological means. This section will briefly describe the somatic embryogenesis-based methods for the recovery of plants following transformation. The reader is referred to several excellent accounts of cotton regeneration from cultured tissues for a more comprehensive understanding of the process (Trolinder and Goodin, 1987; Trolinder and Goodin, 1988a, b; Firoozabady and DeBoer, 1993; Wu *et al.*, 1998; Mishra *et al.*, 2003). Some alternative methods related to the recovery of transgenic plants have been described earlier in the chapter and are not repeated in this section.

The reports included in Table 1 show that somatic embryogenesis from cultures derived from transformed cotyledonary cells or hypocotyls cells remains the most popular means to obtain transgenic cotton (Firoozabady *et al.*, 1987; Umbeck *et al.*, 1987; Cousins *et al.*, 1991; Bayley *et al.*, 1992; Lyon *et al.*, 1993; Sunilkumar and Rathore, 2001; Liu *et al.*, 2002b; Townsend and

Llewellyn, 2002; Townsend *et al.*, 2005; Rathore *et al.*, 2006; Sunilkumar *et al.*, 2006). Also, in some cases where the target tissue for transformation is either hypocotyl/cotyledon-derived embryogenic suspension culture or embryogenic callus culture, the recovery of the transformants is via somatic embryogenesis (Finer and McMullen, 1990; Rajasekaran *et al.*, 1996; Leelavathi *et al.*, 2004). In a majority of these studies, Murashige and Skoog (MS) medium with some variation was used for initiating and maintaining the cultures. A combination of an auxin (2,4-dichlorophenoxyacetic acid (2,4-D), α -naphthaleneacetic acid, or indole-3-butyric acid) and a cytokinin (kinetin or N6-(2-isopentenyl)adenine) is used for callus induction, proliferation, and obtaining embryogenic cultures. Usually, a hormone-free medium in combination with additional KNO₃ is used for somatic embryo development. Some laboratories utilize an intermediate suspension culture phase (Cousins *et al.*, 1991; Bayley *et al.*, 1992; Payton *et al.*, 1997; Wilkins *et al.*, 2004) to hasten embryogenesis and to increase the number of somatic embryos. However, the maintenance of suspension culture necessitates the use of shakers and the method involves pipetting and fractionation steps. These procedures are not only more labor intensive, they add to the risk of contamination and, therefore, many laboratories maintain their cultures on semisolid medium throughout the regeneration process (Firoozabady *et al.*, 1987; Thomas *et al.*, 1995; Sunilkumar and Rathore, 2001; Townsend and Llewellyn, 2002; Rathore *et al.*, 2006). Although cells at the wound site in the cotyledon-, hypocotyl-, or cotyledonary petiole explants are highly amenable to *Agrobacterium*-mediated transformation, the recovery of plants from these cells in cotton depends on somatic embryogenesis. However, this type of regeneration process is genotype dependent, highly labor intensive, and necessitates lengthy culture periods. It is possible to shorten the period between transformation step and the recovery of transgenic cotton plant by using pre-established embryogenic calli or suspensions as the target explants for *Agrobacterium* or the gene gun (Rajasekaran *et al.*, 2000; Leelavathi *et al.*, 2004). However, this procedure necessitates periodic initiation of callus cultures and regular maintenance of embryogenic callus/suspension cultures. In order to bypass the problems encountered with somatic

embryogenesis, direct transformation of cells within the shoot apical meristem has been attempted. These methods with their associated strengths and weaknesses have been described in the previous section.

2.3 Selectable Marker Genes Used for Generating Transgenic Cotton

The list of papers presented in Table 1 suggests that neomycin phosphotransferase II (*nptII*) gene, the first selectable marker gene used to create transgenic cotton, remains a popular choice. Its widespread popularity in obtaining transgenic cotton is due to the fact that kanamycin-based selection is relatively inexpensive and does not have adverse effects on the regeneration of plants from cultured tissues. The hygromycin phosphotransferase (*hpt*) has been used as a selectable marker gene in a few studies suggesting its suitability in generating transgenic cotton (Finer and McMullen, 1990; Li *et al.*, 2004). There are two reports listed in the table involving incorporation of the *bar* (bialaphos resistance) gene into cotton; however, in both cases this gene was not used in the initial selection of transformants (Keller *et al.*, 1997; Wang *et al.*, 2004b). An interesting use of a different herbicide resistance gene, *Arabidopsis-ahas*, was described by Aragao *et al.* (2005), who used it in conjunction with gene gun-mediated transformation of shoot apical meristem in cotton. The *nptIII* gene, present in most of the GM cotton products, has been shown to be safe for both the environment and the consumer. Therefore, it will continue to be used as a selectable marker gene for routine cotton transformation. However, if needed, a variety of means that has been tested in other species is available to generate marker-free transgenic cotton plants (Yoder and Goldsbrough, 1994; Ebinuma *et al.*, 2001; Breitler *et al.*, 2004).

2.4 Reporter Genes Used in Cotton

Chloramphenicol acetyltransferase (*cat*) gene, widely used as a reporter gene in animal systems, was also used in the first published study on cotton transformation (Umbeck *et al.*, 1987). In the same year, Jefferson *et al.* (1987) published

a report describing the use of β -glucuronidase (*gusA*) as a reporter gene in plant systems. This gene allowed monitoring of transformation by either a simple histochemical method or a fluorescence-based, highly sensitive, quantitative assay. The information provided in Table 1 shows that this remains the gene of choice to evaluate various transformation methods as well as for the characterization of promoter activities in various tissues in cotton (Lyon *et al.*, 1993; McCabe and Martinell, 1993; Sunilkumar *et al.*, 2002a; Li *et al.*, 2005). In fact, in studies involving gene gun-mediated transformation of shoot apical meristems where the primary transformants recovered are transgenic chimeras, the selection of transformed tissues was based entirely on the monitoring of *gusA* activity and selective pruning of the nontransformed parts (McCabe and Martinell, 1993). Its use for transgenic research in cotton will continue because of the simple and relatively inexpensive assays to monitor GUS activity. The more recently developed marker GFP gene, which allows noninvasive monitoring of its expression (Chalfie *et al.*, 1994; Haseloff *et al.*, 1997), has not been widely utilized in cotton. Despite its superiority, the need for an expensive microscope with fluorescence capability discourages its widespread use. Nevertheless, the utility and versatility of this reporter gene was elegantly demonstrated by revealing the tissue- and development-specific activity of cauliflower mosaic virus (CaMV) 35S promoter in cotton (Sunilkumar and Rathore, 2001; Sunilkumar *et al.*, 2002b). The use of GFP and other related fluorescence reporter genes will increase in future as the fluorescence microscopy becomes more affordable.

2.5 Traits Introduced into Cotton Through Genetic Transformation

2.5.1 Insect resistance

Bollgard or Bt cotton, introduced by Monsanto in 1996, was one of the first commercially successful GM products (Perlak *et al.*, 1990; Jones *et al.*, 1996; Hardee and Herzog, 1997; Benedict and Altman, 2001). These plants expressed *CryIAc* gene from *Bt* whose protein product (a δ -endotoxin) is toxic mainly to tobacco budworm

and American bollworm. The success of this product provided a powerful demonstration of the power of biotechnology in addressing an important agronomical problem whilst helping the environment by reducing our dependence on harmful chemicals. In fact, the problem of Lepidopteran insect pests is so severe in all cotton-growing areas of the world that Bt cotton technology is usually the first GM crop to receive approval from the respective regulatory agencies. Bollgard II, which in addition to *CryIAc* also contains *Cry2Ab*, became available in 2003 (Micinski *et al.*, 2006; Robinson, 2006). This second *Bt* gene extends the resistance to fall armyworm, beet armyworm, cabbage looper, and soybean looper (Perlak *et al.*, 2001). Syngenta has recently developed a new generation of genes from *Bt* called the vegetative insecticidal protein (VIP; Estruch *et al.*, 1996). The *VIP* gene encodes an exotoxin that is structurally, biochemically, and functionally different from the Bt δ -endotoxins and exhibits insecticidal activity against a variety of Lepidopterans (McCaffery *et al.*, 2006). Another insect-resistant cotton has been developed by Dow AgroSciences by combining *CryIF* and *CryIAc* genes. This product, WideStrike cotton, also confers resistance to several Lepidopteran pests (Bacheler *et al.*, 2006; Micinski *et al.*, 2006). A wider choice of more than one insect resistance genes, especially if they are stacked, will help delay build up of resistance in the target insects.

2.5.2 Herbicide resistance

Roundup Ready cotton, introduced in 1997 by Monsanto, confers resistance to glyphosate-based herbicide (Nida *et al.*, 1996). This trait was engineered by expressing *Agrobacterium* sp. strain CP4 5-enolpyruvylshikimate-3-phosphate synthase (CP4-EPSPS) under the control of FMV 35S promoter. Glyphosate-tolerant cotton helps in the effective management of weeds and was also quickly adopted by cotton growers in the United States. Insect resistance and the herbicide resistance traits are also available in combination. Since their introduction a decade ago, GM cottons with these two traits either combined or separate are grown on 80% of the acreage devoted to cotton in the United States, and their share is rapidly increasing in other cotton-growing

countries (James, 2004). Although Roundup Ready cotton provides sufficient tolerance to glyphosate applications during the vegetative state of plant development, late-stage application of the herbicide causes male sterility due to weak activity of the FMV 35S promoter in male reproductive tissues (Chen *et al.*, 2006). However, this weakness has been overcome by engineering an additional expression cassette that contains the CP4-EPSPS gene under the control of *Arabidopsis* elongation factor-1 α promoter (Chen *et al.*, 2006). This doubled-cassette cotton, that allows safe application of the herbicide well beyond the 5-leaf stage, was marketed as Roundup Ready Flex[®] cotton in 2006. In addition to these two commercially successful traits, there are a number of reports from both industrial and academic laboratories on successful engineering of cotton with useful genes (Table 1). These include genes that confer resistance to four different types of herbicides, namely 2,4-D, bromoxynil, phosphinothricin/bialaphos, and imidazolinone/sulfonylurea (Bayley *et al.*, 1992; Lyon *et al.*, 1993; Panter *et al.*, 1996; Rajasekaran *et al.*, 1996; Keller *et al.*, 1997). Of these, only phosphinothricin/bialaphos-tolerant cotton, developed by Bayer CropScience and marketed by FiberMax under the name LibertyLink[®], is available commercially (Perkins, 2004).

2.5.3 Resistance to pathogens and abiotic stresses

There are some reports on engineering of cotton to confer resistance to various fungal diseases (Murray *et al.*, 1999; McFadden *et al.*, 2000; Emani *et al.*, 2003; Wang *et al.*, 2004b; Rajasekaran *et al.*, 2005). Although these studies appear quite promising, in each case, the transgenic trait confers protection against only a limited spectrum of pathogens. A number of studies have been conducted that attempted to engineer cotton plant to confer resistance to abiotic stresses that include freezing, waterlogging, salt stress, and drought (Ellis *et al.*, 2000; Korniyev *et al.*, 2001, 2003a, b; Logan *et al.*, 2003; Payton *et al.*, 2001; Yan *et al.*, 2004; He *et al.*, 2005; Light *et al.*, 2005). However, these investigations have had varying degrees of success in making the cotton plants tolerant to the intended environmental stresses.

2.5.4 Fiber modification

Cotton is grown mainly for its fiber and, therefore, there is an obvious interest in applying biotechnological tools to alter fiber traits for superior product performance. The desired properties of cotton fiber include strength, fineness, length, and uniformity. Dye binding, wrinkle resistance, and shrinkage resistance are additional characteristics that will help cotton fiber compete effectively against synthetic fibers. The number of genes involved in controlling some of these traits is likely to be large and the mechanism controlling these characteristics is expected to be complex. As more genes involved in fiber initiation, elongation and development become available and are characterized, their coding sequences and promoters will be used in future for engineering cotton to address issues related to fiber quality improvement. Nevertheless, some interesting work to modify cotton fiber has been already conducted by scientists at Agracetus, Inc. and others. Three different strategies were used to alter fiber characteristics (John, 1998, 1999). The first approach involved reduction in the expression of certain fiber-specific genes; however, this manipulation did not result in any obvious changes in the fiber properties (John, 1999). Endogenous levels of hormones play important roles in the growth and development of various cell types including fiber cells. However, genetically engineered, enhanced levels of auxin and cytokinins did not influence fiber elongation, strength, or micronaire (John, 1999). The third approach included synthesis of novel biomaterials in the fiber. This research involved expression of genes from *Alcaligenes eutrophus* in developing cotton fibers that resulted in the deposition of poly-D-(–)-3-hydroxy-butyrate (PHB) in their lumens (John and Keller, 1996; Rinehart *et al.*, 1996). This modification resulted in a fiber with altered thermal properties such that its insulating characteristics were enhanced (Chowdhury and John, 1998). Although this modified fiber cotton has not been commercialized, this successful engineering feat demonstrates the feasibility of improving cotton fiber in ways that is not possible by traditional breeding methods. Recent studies by some other groups involving manipulation of fiber-specific gene expression in cotton also suggest that it will be possible to genetically engineer cotton

to modify its fiber characteristics (Ruan *et al.*, 2003; Arioli, 2005; Li *et al.*, 2005). A number of laboratories around the world are conducting gene isolation/identification/characterization, EST sequencing, and functional genomics studies related to the cotton fiber (John and Crow, 1992; Wilkins, 1993; Wan and Wilkins, 1994; Hasenfratz *et al.*, 1995; John, 1995; John and Keller, 1995; Ma *et al.*, 1995, 1997; Pear *et al.*, 1996; Song and Allen, 1997; Shimizu *et al.*, 1997; Orford and Timmis, 1997; Kawai *et al.*, 1998; Orford and Timmis, 1998; Smart *et al.*, 1998; Delmer, 1999; Loguercio *et al.*, 1999; Orford *et al.*, 1999; Whittaker and Triplett, 1999; Wilkins and Jernstedt, 1999; Liu *et al.*, 2000; Orford and Timmis, 2000; Cui *et al.*, 2001; Delmer and Haigler, 2002; Harmer *et al.*, 2002; Li *et al.*, 2002a; Zhao and Liu, 2002; Ji *et al.*, 2003; Suo *et al.*, 2003; Zhang *et al.*, 2003; Zhu *et al.*, 2003; Arpat *et al.*, 2004; Kim and Triplett, 2004; Ruan *et al.*, 2004; Sun *et al.*, 2004; Wang *et al.*, 2004a; Zhang *et al.*, 2004; Haigler *et al.*, 2005; Hsu *et al.*, 2005; Humphries *et al.*, 2005; Ruan, 2005; Wilkins and Arpat, 2005; Wu *et al.*, 2005b; Udall *et al.*, 2006; Wu *et al.*, 2006b; Yang *et al.*, 2006; Burr, 2000). Expression of only a handful of the genes identified from these investigations has been studied in detail thus far. Functional analysis involving overexpression and/or RNAi-mediated silencing of individual genes should be possible now that cotton transformation has become routine in several laboratories around the world. As additional genes (and their promoters) that are involved in fiber growth and development are characterized, these will be employed to genetically engineer the cotton plant to obtain desired fiber properties.

2.5.5 Cottonseed modification

An important and abundant byproduct of fiber production is the cottonseed. A substantial portion of the global cottonseed output is used for edible oil extraction. Gene silencing technologies have been used to alter cottonseed oil fatty acid composition in favor of higher oleic acid. Sunilkumar *et al.* (2005) used antisense technology to double the oleic acid from a wild-type level of ~15% to ~30% while reducing the linoleic acid level from ~55% to ~35%. A more powerful RNAi-mediated silencing of the same target gene

resulted in a fivefold increase in oleic acid level and a concomitant reduction in linoleic acid content (Liu *et al.*, 2002b). In the same study, RNAi-mediated down-regulation of the *ghSAD-1* gene resulted in >10-fold increase in stearic acid levels in cottonseed oil. These results show the possibility of improving the quality of cottonseed oil by modifying a biosynthetic pathway in a tissue-specific manner.

In addition to oil, cottonseed contains 23% protein that is of relatively high quality. Worldwide cottonseed output can potentially meet the protein requirements of 500 million people. However, the ability to utilize this protein-rich resource for food is hampered by the presence of toxic terpenoid, gossypol, which is unique to the tribe Gossypieae. This cardio- and hepatotoxic terpenoid, present in the cottonseed glands, renders the seed unsafe for human and monogastric animal consumption. Since traditional breeding methods may not be able to bring about a significant reduction in gossypol in a seed-specific manner, biotechnological approaches are being tested in many laboratories around the world to solve this long-standing problem of cottonseed toxicity. Most of these attempts over the last decade have been unsuccessful (see Townsend *et al.*, 2005 and references therein). However, in a recent breakthrough, the feat of selective and significant reduction of gossypol level in the cottonseed through metabolic engineering has been finally achieved (Sunilkumar *et al.*, 2006). This study utilized RNAi to disrupt gossypol biosynthesis in cottonseed tissue by interfering with the expression of the δ -cadinene synthase gene during seed development. Some of the RNAi lines obtained showed a 98% reduction in the levels of gossypol in the seed while maintaining this and other protective terpenoids in all other parts of the plant at the wild-type concentrations where they provide protection against insects and diseases. Several members of the δ -cadinene synthase gene family have been cloned from both, the diploid, *G. arboreum* and the tetraploid, *G. hirsutum* (see Townsend *et al.*, 2005 and references therein). In addition, genes encoding other enzymes in the terpenoid biosynthesis have been obtained from cotton (Liu *et al.*, 1999, 2002a; Luo *et al.*, 2001). Thus, it may also be possible to utilize one or more of these genes to modulate terpenoid biosynthesis in the seed or elsewhere in the cotton plant.

The results from oil and gossypol studies suggest that cotton plant, in addition to meeting the clothing requirements of humanity, can also play an important role in meeting its nutritional requirements in the future.

2.6 Intellectual Property Rights Related to Genetic Modification of Cotton

Plant biotechnology industry largely depends on the revenues generated by the sale of seeds from the crop plants that have been genetically modified. Currently, genetic modification involves introduction of a novel trait by overexpression of homologous or heterologous gene(s) and/or suppression of endogenous plant gene(s). Therefore, the basic research tools and techniques required for plant genome modification such as the methods for plant transformation and regeneration, genes that confer useful traits, and the DNA sequences needed to regulate the expression of the transgenes in either a constitutive-, tissue-specific, or temporal manner are the potential targets for obtaining patent rights. By creating biotechnology products and/or enabling technologies, companies as well as the academic laboratories have made contributions to the intellectual property resource for cotton improvement over the last two decades. This section will highlight some of the key patents that have been issued for cotton transformation techniques, the promoters and genes isolated from cotton for its improvement, and the genetically altered cotton plants with desired traits (Tables 2, 3, 4, and 5).

2.6.1 Cotton transformation techniques

The first paper on cotton transformation was published in 1987 by researchers from Agracetus (Umbeck *et al.*, 1987). They filed and obtained patents for this commercially valuable technique in several cotton growing countries including the United States, Brazil, China, and India. The company was granted a US patent on transgenic cotton plant produced by *Agrobacterium*-mediated transformation of hypocotyl segments followed by recovery of transformants via somatic

embryogenesis (US 5,004,863, April 1991; Table 2). Subsequently, upon filing a continuation application the company successfully obtained a broader patent (US 5,159,135). This patent covered all genetically engineered cotton plants and seeds regardless of the gene used for the transformation. Following the controversies over the broad nature of its coverage, the patents granted initially in the United States and India, were revoked in both countries in 1994 (NBIAP News Report, January 1995 (<http://www.isb.vt.edu/news/1995/news95.jan>); van Wijk, 1995). However, both the United States patents have been re-examined by the US Patent and Trademark Office (USPTO) and granted patentability of all of the claims listed in the original patents. Monsanto, in 1996, acquired Agracetus with its plant biotechnology assets including the key patent on cotton transformation. In 2001, Aventis CropScience was added as a joint owner of this cotton transformation patent as part of the settlement for the pending lawsuit filed against Monsanto (<http://www.seedquest.com/News/releases/usa/Monsanto/n3410.htm>). Bayer CropScience acquired Aventis CropScience in 2002, thereby becoming a co-owner of this patent.

After the first patent on cotton transformation was granted, various alternative methods were developed to create transgenic cotton plants. These involved the use of different gene transfer techniques or modifications in the original cotton transformation protocol such as use of a tissue explant other than hypocotyl for transformation, use of novel methods for regeneration of the transformed cells, transformation of cotton cultivars other than Coker, etc. Patents on the use of alternate explants for the *Agrobacterium*-mediated transformation protocol were obtained by several companies. A method developed by Calgene used *Agrobacterium* or the gene gun to transform hypocotyl segments excised from dark-grown cotton seedlings (US 5,846,797). Although transgenic plants were regenerated in this case via the usual somatic embryogenesis process, this method relied on media that was devoid of the phytohormones during co-cultivation and embryogenesis. Production of transgenic cotton plant from *Agrobacterium*-transformed cells in the “transition-region” of the cotton seedling has been patented by Southplains Biotechnologies

Table 2 Patents related to cotton transformation methods

Patent number	Issue date	Inventors	Assignee	Patent title
US 5,004,863	April 02, 1991	Umbeck	Agracetus Inc., USA	Genetic engineering of cotton plants and lines
US 5,159,135	October 27, 1992	Umbeck	Agracetus Inc., USA	Genetic engineering of cotton plants and lines
US 5,164,310	November 17, 1992	Smith <i>et al.</i>	Texas A&M University System	Method for transforming plants via the shoot apex
WO 97/43430	November 20, 1997	Chapman <i>et al.</i>	University of North Texas	A rapid in vitro regeneration scheme of cotton plants compatible with <i>Agrobacterium</i> -mediated transformation
US 5,846,797	December 8, 1998	Strickland	Calgene Inc, USA	Cotton transformation
EP 531,506	December 16, 1998	McCabe and Martinell	Monsanto Co., USA	Particle-mediated transformation of cotton

Inc., USA (US 5,986,181). Bayer BioScience was granted a patent on *Agrobacterium*-mediated transformation of embryogenic callus itself that was derived from a hypocotyl tissue from the cotton seedlings (US 6,483,013). Furthermore, their method involved transformation in the presence of a plant phenolic compound (acetosyringone). Mycogen Corp., USA patented a protocol involving *Agrobacterium*-mediated transformation of hypocotyl, cotyledon, or immature zygotic embryo from the Acala cotton varieties (US 6,573,437). In subsequent patents, the company claimed the

use of the same method to transform additional cultivable cotton varieties (US 6,620,990, US 6,624,344, and US 6,660,914). The Institute of Molecular Agrobiolgy, Singapore was granted worldwide patents on cotton transformation that involved *Agrobacterium*-mediated transformation of callus tissues obtained from fibrous root explants or petiole explants (WO 00/53783 and WO 00/77230). In each case, the transgenic plants were regenerated via somatic embryogenesis.

As mentioned earlier, somatic embryogenesis is one of the limiting steps for the development of a

cotton transformation protocol that is universally applicable to a range of cotton cultivars. Therefore, several attempts were made to develop a cultivar-independent transformation method either by using shoot apex as the explant or by using direct organogenesis as a means to regenerate plants. McCabe and Martinel (EP 531,506) produced a transgenic cotton plant from the embryonic axis following transformation of the shoot apical meristem with a gene gun. The method was originally developed at Agracetus; however, the patent has been awarded to Monsanto following the acquisition. *Agrobacterium*-mediated transformation of shoot apices from monocots and dicots including the cotton plant was patented by Smith *et al.* (US 5,164,310). A variation on this method that involved treatment of apical shoot tips at 2–8 °C for 24 h prior to transformation with *Agrobacterium* or gene gun was patented by Cotton Incorporated (US

7,122,722). Syngenta Participations AG obtained a patent for a method of producing transgenic plants via multiple shoot formation from shoot meristem of several dicot plants including cotton (US 6,858,777). Reichert *et al.* of Mississippi State University describe a method for organogenic regeneration of cotton plants from leaf explants (US 5,998,207) or hypocotyl explants (US 6,479,287) that may be transformed with *Agrobacterium* or the gene gun. University of North Texas has been granted a patent on a regeneration method using explants of apical and/or nodal meristematic tissues that is compatible with *Agrobacterium*-mediated transformation (WO 97/43430). With the exception of the gene gun-based method patented by Agracetus/Monsanto (EP 531,506), the practical utility of the other alternative methods that are designed to bypass somatic embryogenesis remains uncertain in generating transgenic cotton plants in a routine manner (see

discussion related to the transformation of cells within the apical meristem in Section 2.1.2).

Dow Agrosociences LLC, USA used an alternate, nonconventional method to transform cotton. A US patent issued to the company describes the use of a whisker (silicon carbide) system for introducing transgenes into embryogenic callus cultures derived either from hypocotyl or cotyledon tissue from a cotton seedling (US 6,730,824). In a patent assigned to the Secretary of Agriculture, USA, a method to transform cotton pollen by *Agrobacterium* followed by pollination to obtain transgenic cottonseed is described. Using this method, they obtained one transgenic seed for every 3000 seeds tested (US 5,929,300).

2.6.2 Genes obtained from cotton

As a first step toward fiber quality improvement via genetic engineering, identification of genes involved in the development of fiber has been the primary focus of cotton molecular biologists. A

list of patents related to the genes obtained from cotton has been provided in Table 3.

Several useful genes that expressed specifically during various stages of fiber development have been identified in the last two decades. A joint patent was awarded to Texas Tech University and Toyo Boseki Kabushiki Kaisha, Japan for fiber-specific genes that expressed during fiber elongation stage (US 5,932,713 and US 6,166,294). Hasegawa *et al.*, isolated a transcription factor-like gene that was expressed during fiber formation in cotton (US 6,169,174). Wilkins (University of California) isolated six genes encoding MYB transcription factors from cotton (US 6,828,476). Expression of two of the MYB genes in transgenic tobacco increased the number, distribution, density, length, and morphology of trichomes. The patent covers the use of these genes to improve cotton fiber quality. Wilkins also isolated the following genes from cotton: phosphoenol pyruvate carboxylase, expansin, endoglucanase, xyloglucan endoglycosyltransferase, and pectin methyl esterase (US 7,060,874). Overexpression of

expansin gene in a constitutive manner enhanced the fiber length and yield. The patent covers the coding sequences and the promoters from these genes as well as the use of these components to modify cotton fibers. Calgene LLC owns the intellectual property rights to cotton cellulose synthase gene, *CelA1* (US 6,271,443 and US 6,576,818). They isolated the catalytic subunit of cellulose synthase gene from cotton that expressed in developing fibers at the onset of secondary wall cellulose synthesis. Calgene obtained a worldwide patent on two cotton fiber-specific transcriptional factor genes *rac13* and *4-4* (WO 96/40924). Australian National University has been granted a patent on the catalytic subunit of cellulose synthase gene from various species including a complementary DNA (cDNA) sequence obtained from cotton (US 6,495,740). Mississippi State University patented cotton fiber-specific lipid transfer protein gene *GH3* (US 5,792,933). A fiber-specific actin gene, *CFACT1* and a β -tubulin gene, *CFTUB2* from cotton were patented by Temasek Life Sciences Laboratory, Singapore (US 6,995,256 and US 6,998,478). Haigler *et al.* (Texas Tech University) isolated genes encoding endogenous chitinase from cotton that expressed during the secondary wall deposition in cotton fibers (US 7,098,324).

2.6.3 Promoters isolated from cotton

The upstream regulatory sequences of the fiber specific and other genes from cotton constitute good source of promoters that can be used to control the expression of transgenes in desired cells/tissues or at certain stage of development. The promoters from the following fiber-specific genes isolated from cotton have been patented: lipid transfer protein genes *GH3*, *PLTP6*, and *PLTP12* (US 5,792,933); *KC03*, *KC18*, *KC22*, and *Gh3* genes (US 6,259,003); expansin gene that is expressed in developing fiber (US 6,566,586); cellulose synthase gene *CelA1* (US 6,576,818); endochitinase gene that specifically expressed during secondary wall deposition (US 7,098,324); actin gene (US 6,995,256); β -tubulin gene (US 6,998,478); *E6-3B* and *FbLate-2* genes (US 6,096,950); *FbLate* gene (US 6,211,430); and transcription factor genes *rac1* and *4-4* and a lipid transfer protein gene *ltp* (WO 96/40924).

In addition to the fiber specific promoters, a few other cotton promoters have been patented. The promoter region from the genes encoding the small subunit of ribulose biphosphate carboxylase *rbc-gY* and *rbc-gX* from cotton were patented by Novartis Finance Corporation (US 6,040,504). Temasek Life Sciences Laboratory, Singapore obtained a patent for an anther-specific promoter from the *CoFS* gene from cotton (US 7,132,526). A list of patents related to the promoters obtained from cotton has been provided in Table 4.

2.6.4 Genetically engineered cotton plants

A list of patents related to genetically engineered cotton plants has been provided in Table 5.

2.6.4.1 Fiber quality and productivity improvements

Fiber length, strength, and fineness are the three top qualities that determine value of the fiber in the textile industry. Several patents have been issued on the enhancement of some of these qualities by expressing certain genes in cotton fibers. Agracetus obtained patents on the introduction of fiber-specific promoter::reporter gene sequences as well as coding sequences of fiber-specific genes into the cotton genome (US 5,495,070 and US 5,521,078). Agracetus also expressed peroxidase gene in the lumen of seed floss fiber cell for the purpose of increasing the fiber strength (US 5,608,148 (Agracetus), US 5,869,720 (Monsanto)). They also obtained patents on the isolation of fiber-specific genes and their promoters as well as their overexpression/suppression in cotton fiber (US 5,597,718 (Agracetus), US 5,620,882 (Agracetus), and US 5,981,834 (Monsanto)). Calgene LLC patented a method to alter fiber dimension and strength by expressing isopentenyl transferase gene in cotton ovule tissues (US 6,329,570). Haigler and Holaday (Texas Tech University) patented a method for improving various fiber qualities by overexpressing or suppressing sucrose phosphate synthase gene in cotton fibers (US 6,472,588). Furthermore, these researchers were awarded a second patent that described a method to increase the ratio of cellulose to total dry weight components of cotton plants by expressing sucrose phosphate

synthase gene, thereby enhancing the yield and fiber quality (US 7,091,400). Joint patents awarded to scientists from Texas Tech University and Toyo Boseki Kabushiki Kaisha, Japan, described a method to enhance the fiber qualities such as length, fineness, or strength by expressing genes coding for peroxidase (US 6,559,363), catalase (US 6,563,022), or endoxyloglucan transferase gene from cotton (US 7,053,270) in cotton fibers.

2.6.4.2 Fatty acid manipulation to modify cottonseed oil

Cotton plant is also an excellent source of oil in addition to being a major source of fiber. However, cottonseed oil contains high levels of polyunsaturated fatty acids and high levels of palmitic acid. Green *et al.* (CSIRO) modified the fatty acid composition of cottonseed oil by reducing the expression of endogenous *GhFAD2-1* or *GhSAD-1* in cottonseed using various gene-silencing techniques (US 6,974,898).

2.6.4.3 Insect-resistant cotton plants

Monsanto produced transgenic cotton plants, commercially marketed as Bollgard cotton, that are resistant to Lepidopteran insect pests by expressing Bt crystal protein gene *CryIAC* (US 5,880,275). They also created and are marketing Bollgard II cotton with broader spectrum resistance against insects by adding a second Bt gene *Cry2Ab* (US 5,338,544; Perlak *et al.*, 2001) to the plants containing *CryIAC* gene. Agracetus had also produced transgenic cotton plants containing a Bt δ -endotoxin gene that provided resistance to *Heliothis zea* (US 5,608,142). Mycogen Corp. transformed cotton with pesticidal genes that encode barley, hevein, or nettle lectins (US 6,710,228). In 2005, Mycogen Plant Science, Inc. was awarded a patent that described creation of a transgenic cotton plant expressing crystal protein gene from *Bt* strain HD-1 or HD-73 (US 6,943,282). A different approach using a cDNA encoding floral defensin from *Nicotiana glauca* was used by Hexima, Ltd. to enhance the resistance of cotton plants to *Helicoverpa armigera* larvae (US 7,041,877). Recently, DOW

AgroSciences have begun to market WideStrike cotton that contains a combination of *CryIAC* and *CryIF* (US 5,188,960, US 5,827,514, US 6,218,188). As mentioned earlier, VIP is a new generation of insecticidal protein with a different mode of action. Syngenta Biotechnology Inc. and Delta & Pine Land Company are developing a transgenic cotton, VipCot™ (patent pending), by expressing *vip3A* gene from *Bt* in addition to *CryIAb*. This cotton provides a broader spectrum resistance against Lepidopteran insects.

2.6.4.4 Herbicide-resistant cotton plants

Monsanto patented a method for producing transgenic cotton that confers resistance to herbicide thiazopyr by expressing rabbit liver esterase gene (US 6,107,549). In 1996, Monsanto also produced and marketed transgenic cotton plants (Roundup Ready cotton) resistant to the herbicide glyphosate by expressing EPSPS gene from *Agrobacterium* sp. strain CP4 (US 5,633,435). Recently, Monsanto has released an improved glyphosate-resistant transgenic cotton variety called Roundup Ready Flex cotton. As mentioned earlier, the weakness related to male sterility in the Roundup Ready cotton has been overcome by engineering an additional expression cassette that contains the CP4-EPSPS gene under the control of *Arabidopsis* elongation factor-1 α promoter. This modification provides the male reproductive system an enhanced level of tolerance to glyphosate, thereby preventing the early boll loss that was observed in the Roundup Ready plants. Monsanto also obtained a patent on a cotton plant that was co-transformed with glyphosate oxidase (GOX) gene and *phnO* gene encoding AMPA-N-acetyltransferase. Expression of *phnO* gene conferred protection against bleaching that is induced by the degradation product, AMPA, that accumulates as a result of oxidation of glyphosate by GOX (US 6,448,476). Glyphosate-tolerant transgenic cotton plant was also produced by Mycogen Corporation by expressing an altered form of *AroA* gene from *Salmonella typhimurium* (US 6,753,463). Bayer BioScience obtained a patent in 2004 on the production of glufosinate herbicide-tolerant transgenic cotton plants by expressing *bar* gene from *Streptomyces*

hygrosopicus (US 6,818,807). This product is being marketed as LibertyLink cotton since 2004. An alternative strategy to control weeds through the use of a modified protoporphyrinogen oxidase gene has been patented by Novartis Finance Corporation (US 6,308,458).

2.6.4.5 Cotton fiber as a platform for the expression of novel proteins

In addition to its use in manufacturing textiles, cotton fiber can be utilized as a system for producing and storing useful proteins. Agracetus developed a system in which an industrial enzyme was expressed in the lumen of cotton fibers. The expectation is that the fibers containing the immobilized enzyme, packed into reaction columns can be used in industrial enzymatic processes. A US patent awarded to the company described the immobilization of recombinant β -glucuronidase and parathion hydrolase in transgenic cotton fiber (US 5,474,925). Furthermore, Monsanto created transgenic cotton that makes bioplastic molecule PHB in the fiber by expressing genes that encode ketothiolase, acetoacetyl CoA reductase and PHB synthase (US 5,602,321). The fibers from these plants had altered flexibility, stiffness, strength, absorbency, and thermal properties.

2.7 Benefits of Genetically Modified Cotton

Insect-resistant, Bollgard cotton (Jones *et al.*, 1996; Hardee and Herzog, 1997; Perlak *et al.*, 2001), herbicide (Buctril®)-resistant, BXN57 cotton (Panter *et al.*, 1996), and herbicide (glyphosate)-resistant, Roundup Ready cotton (James and Krattiger, 1996) were the first GM cottons marketed in the United States in 1996/1997. Cotton garnered the largest acreage for the first year of commercialization of GM crops in the United States (James, 1997). In the year 2004, GM cotton was planted on 80% of the US, 66% of the Chinese, 80% of the Australian, and 85% of the South African cotton acreage (James, 2004). Often, GM cotton is the first genetically engineered crop to receive approval for commercial planting in many other countries.

Although Bt-cotton varieties have been cultivated in the major cotton producing countries for

only 10 years or less, studies conducted thus far indicate that economic benefits to the farmers have been significant (Benedict and Altman, 2001; Pray *et al.*, 2002). There were substantial reductions in the number of pesticide applications in the United States following adoption of Bt-cotton. In six cotton-growing states in the United States following the introduction of Bt cotton in 1996, the number of insecticide treatments per season dropped from an average of 4.85 in 1995 to 1.88 in 1998 (Betz *et al.*, 2000). Similarly, following the introduction of Bt cotton, reductions of 3–5 sprays per ha per season have occurred in Australia (Benedict and Altman, 2001). In the developing countries, Bt cotton has increased the yields while decreasing the cost of production by reducing the pesticide use (Pray *et al.*, 2002; Brookes and Barfoot, 2005a; Gomez-Barbero and Rodriguez-Cerezo, 2006). Interestingly, smaller farms consistently obtained larger increases in net income compared to the larger farms in China by growing Bt cotton. Following its introduction in 2002 when Bt cotton was grown on 50 000 ha in India, the insect-resistant cotton plants were cultivated by 2.3 million small farmers on 3.8 million hectares in the year 2006 (James 2007). The average yield of cotton in India, one of the lowest yields in the world, increased from 308 kg ha⁻¹ in 2001–2002 to 450 kg ha⁻¹ in 2005–2006. Most of the improvement in yield has been attributed to the adoption of Bt cotton (James, 2007). The cost of pest control also fell in the developed countries due to adoption of insect-resistant cotton. However, the benefits of fewer pesticide applications, to some degree, were offset by the higher cost of GM cottonseeds resulting in smaller gains in the farm income for the growers, especially in the United States (Brookes and Barfoot, 2005a; Gomez-Barbero and Rodriguez-Cerezo, 2006). Nevertheless, the rapid adoption of GM varieties by cotton growers in both developed and developing countries clearly suggests significant benefits to the farmers. There have been many obvious and direct benefits of the Bollgard cotton including reduced use of broad-spectrum insecticides, lower farming risks and production costs, and better yields. An excellent analysis of these as well as indirect and less tangible advantages of this technology has been provided by Edge *et al.* (2001). Globally, the farm level impact of using Bt cotton was \$1.47

billion in the year 2004 (Brookes and Barfoot, 2005a, b).

Roundup Ready cotton, introduced in 1997, was also immediately accepted by cotton growers in the United States. As discussed earlier, the limitations of the original Roundup Ready cotton are expected to be overcome by Roundup Ready Flex cotton introduced in 2006. An alternative weed management system, LibertyLink cotton developed by Bayer CropScience, became commercially available in 2004. This cotton has been engineered to resist glufosinate ammonium-based herbicide, Ignite[®] (also called Liberty[®], Finale[®], Basta, and Rely[®]). Herbicide-tolerant cotton helps in the effective management of weeds and benefits the environment by encouraging the adoption of soil conservation practices. The enhancement in no-till acreage has been higher for cotton compared to any other crop (Sankula, 2006). This increase has largely been attributed to the availability of herbicide-resistant cotton. In addition, glyphosate, used on Roundup Ready cotton, is less toxic and more environmentally benign compared to the herbicides it replaces (Fernandez-Cornejo and Caswell, 2006). Herbicide-resistant cotton varieties are being grown in the United States, Australia, and South Africa and their share of the global cotton acreage is likely to increase in future (Brookes and Barfoot, 2005a).

Although real and significant, the benefits conferred by the two GM traits to the environment and in saving labor and fuel costs are not easily quantified (Gomez-Barbero and Rodriguez-Cerezo, 2006). However, analyses published by Edge *et al.* (2001) and Brookes and Barfoot (2005b) provide informative accounts of the impact of GM crops on the economics and the environment. GM varieties are expected to continue increasing their share of the global cotton acreage in the future as more Indian and Chinese farmers accept and adopt the GM technology and as more countries approve planting of GM crops.

2.8 New Technological Advances and Their Role in Cotton Improvement

Most transgenic crop plants including cotton have been generated by random integration of transgenes into their nuclear genomes. Although the commercial success of these first generation

GM crops has been astounding, new advances in biotechnology, molecular biology, and genomics promise even larger array of products in the future that are based on the alteration of organelle genome, more subtle changes in the nuclear genome in a very precise manner or gene knockout/silencing.

Transformation of the plastid genome has been reported for cotton recently (Kumar *et al.*, 2004). Compared to nuclear transformation, chloroplast transformation is more difficult and less efficient; however, it offers many advantages, including transgene containment because of maternal inheritance and a high level of consistent expression. By expressing two selectable marker genes to detoxify kanamycin in the green and nongreen tissues, Kumar *et al.* (2004) were able to regenerate cotton plants from cells containing plastids that were stably transformed. These transformants were fertile and more importantly, showed maternal inheritance of the transgene. Because of the lower efficiency and complexity of the plastid transformation system, widespread adoption of this technology is currently unlikely; however, in cases where a high level of transgene expression and/or its containment are desired, it will play an important role.

Modification of endogenous genomic sequences by homologous recombination or gene targeting has a lot of potential in plant improvement. Although efforts are being made to improve gene targeting in plants, it remains inefficient in comparison to what has been achieved in animal systems (Iida and Terada, 2005). However, in combination with a technology based on the use of designed zinc finger nucleases that can efficiently create double stranded breaks in a desired portion of the DNA, the efficiency of the targeting process can be substantially improved (Bibikova *et al.*, 2003). Recent successes with model plant species raise the possibility that the cotton genome can also be modified using this novel technology (Wright *et al.*, 2005). Another strategy for genome modification makes use of self-complementary, chimeric RNA/DNA oligonucleotides to create specific 1–2 bp alteration. This technology has been successfully used to mutate a gene encoding an enzyme of the branched-chain amino acid pathway in various plant systems to confer resistance to either imidazolinone or sulfonylurea herbicides (Beetham *et al.*, 1999; Zhu *et al.*, 1999;

Kochevenko and Willmitzer, 2003). Although promising, the utility of each of these technologies, especially to introduce recessive modifications, may be complicated by the fact that a majority of the commercial cotton varieties grown today are tetraploid.

The two examples of RNAi-mediated modification of seed-oil fatty acid composition and gossypol elimination show clearly that this newly discovered gene-suppression mechanism will play an important role in the future improvement of cottonseed. Once the genes involved in controlling various aspects of fiber growth and development are identified, RNAi will be an extremely valuable tool in engineering the desired characteristics in the fiber. In addition to the use of RNAi to improve the properties of the fiber and the seed, it may be possible to use this powerful gene silencing mechanism to address the problem of parasitic nematodes in cotton. Yadav *et al.* (2006) transformed tobacco plants to express dsRNA against important genes of an RKN that led to a virtual elimination of the target messenger-RNA (mRNA) in the parasite and significant resistance in the host plant. In another recent report, Huang *et al.* (2006) describe results of *in vivo* expression of dsRNA in *Arabidopsis* targeting an RKN gene that encodes *I6D10*, a secretory peptide essential for the nematode parasitism of the plant. These transgenic plants showed significant resistance to four major RKN species. It should be possible to engineer cotton plants in a similar way by targeting these particular genes or other gene(s) essential for parasitism to confer resistance to RKN.

2.9 Regulation of Agricultural Biotechnology

As research in plant biotechnology in the early 1980s geared toward developing commercial applications, the US government moved to provide guidance and a comprehensive regulatory oversight system. In 1984, the US government developed a coordinated framework to regulate agricultural biotechnology based on legislation that was already in place to protect the environment, agriculture, and food. This framework ensured that plants and plant products produced by biotechnology were as safe as their conventional counterparts for the environment, for agriculture,

and for use as food or feed. Since the authority to regulate agricultural biotechnology was based on existing laws, the involvement of each regulatory agency depends on the specific product and phase of product development.

2.9.1 US agencies involved in the regulation of agriculture biotechnology

United States Department of Agriculture (USDA), Food and Drug Administration (FDA), and Environmental Protection Agency (EPA) are the primary agencies that regulate plants and products derived from them that are generated using modern biotechnology. Details on the regulatory aspects related to agriculture biotechnology in the United States can also be obtained from the following links:

- <http://pewagbiotech.org/resources/issuebriefs/1-regguide.pdf>
- <http://www.agbioforum.org/v3n4/v3n4a15-belson.htm>

2.9.1.1 USDA

The Animal and Plant Health Inspection Service (APHIS) branch of USDA regulates agricultural biotech plants under the Plant Protection Act, a consolidation of 10 previous laws including the Plant Pest Act, the Plant Quarantine Act, and the Noxious Weed Act. The goal of the Plant Protection Act and its preceding acts is to protect US agriculture from the introduction of pests. Using the broad authority provided in the Plant Protection Act, plants that are genetically engineered are considered regulated articles under the APHIS regulations (7 CFR Part 304), if they meet the following definition:

Any organism which has been altered or produced through genetic engineering, if the donor organism, recipient organism, or vector or vector agent belongs to any genera or taxa designated in Section 340.2 and meets the definition of plant pest, or is an unclassified organism and/or an organism whose classification is unknown, or any product which contains such an organism, or any other organism or product altered or produced

through genetic engineering which the (APHIS) Administrator determines is a plant pest or has reason to believe is a plant pest.

For any biotech plant meeting the definition of a regulated article, one must obtain approval from APHIS prior to importation, interstate movement, field release, or commercialization of the product. For details check the following websites: <http://usbiotechreg.nbi.gov/roles.asp> and <http://www.aphis.usda.gov>.

2.9.1.2 FDA

FDA has authority under the Federal Food, Drug, and Cosmetic Act to ensure the safety and wholesomeness of most foods, except meat, poultry, and eggs, including foods developed through modern biotechnology. Based on this authority, FDA issued a policy in 1992 on the assessment of the safety of "Foods Derived from New Plant Varieties" that was based on existing food law and required that genetically engineered foods meet the same rigorous safety standards required of all other foods. FDA's biotechnology policy treats genetically engineered substances that are intentionally added to food as food additives if they are significantly different in structure, function, or amount than substances currently found in food. For details check the following website: <http://www.cfsan.fda.gov>.

2.9.1.3 EPA

The BioPesticides and Pollution Prevention Division (BPPD) branch of the Office of Pesticide Programs (OPP) regulates the distribution, sale, use, and testing of plants and microbes producing pesticidal substances, including biotech plants, under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), the Federal Food, Drug and Cosmetic Act (FFDCA), and the Food Quality Protection Act (FQPA). The goal of these acts is to protect human health and to safeguard the natural environment. EPA ensures the safety of pesticides, both chemical and those that are produced biologically. This includes pesticidal proteins that are produced *in planta* such as Bt proteins. Under the FFDCA, EPA sets tolerance limits (safe upper bounds) for substances used as

pesticides on and in food and feed, or establishes an exemption from the requirement of a tolerance (any level is assessed to be safe). EPA also establishes tolerances for residues of herbicides used on herbicide-tolerant crops that create novel use patterns. For details check the following website: <http://www.epa.gov/pesticides>.

2.9.2 Regulatory oversight during product development in the US

Initial regulatory oversight for development and testing of biotech products in the laboratories and growth chambers are overseen by local peer-reviewed committees known as Institutional Biosafety Committees (IBCs). Such committees are mandatory for institutions that receive federal funding to support their biotech research and are used widely in the private sector on a voluntary basis. These committees are responsible for ensuring that the recombinant DNA research conducted or sponsored by the institute is compliant with the National Institutes of Health Guidelines for research involving recombinant DNA molecules (59 Federal Register 34496). For details see the article: http://www4.od.nih.gov/oba/rac/guidelines_02/NIH_Gdlnes.lnk_2002z.pdf.

For importation, interstate movement, or testing biotech plants in the field, approval must be obtained from USDA either in the form of a permit or notification, a streamlined version of the permit. The applicant must identify the plant species, genetic elements, the researchers, and locations of trials. Both the permit and notification process impose requirements to make certain that the movement of biotech material or fields trials are conducted in a manner that will ensure containment of the material, and that the material does not persist in the environment and thus does not negatively impact agriculture or the environment. For importation and interstate movement, precautions include clear markings for identification and double packaging for containment. For field trials, typical precautions include clearly marking the plot area, isolating the regulated plants from sexually compatible relatives, and monitoring for volunteer plants for an appropriate amount of time following the trial. If the size of the trials reaches 10 acres per

assessment of efficacy per pest, and the plant produces a pesticidal trait, an Experimental Use Permit may be required by EPA for such field testing and shipment of materials.

The field trial stage not only allows one to evaluate the performance of the biotech plant but also allows one to collect field data and samples for further study and analyses that will be required by the regulatory agencies if a request to commercialize the biotech plant is pursued.

2.9.3 Regulatory authorizations to allow for commercialization in the US

After collecting laboratory and field data on the biotech plant, documents may be submitted to the regulatory agencies requesting authorizations that allow the biotech plant to be commercialized. For example, cotton is grown as a row crop. So, USDA and EPA address the impacts on the environment and agriculture. While FDA addresses the use for food and feed of cottonseed and its products such as cottonseed oil and meal.

USDA. To allow for unconfined plantings, such as commercial use, biotechnology-derived plants must be deregulated by USDA-APHIS by petitioning the agency in a formal submission. The deregulation request (also referred to as a petition for a determination of nonregulated status) asks APHIS to no longer consider the biotech plant to be a regulated article and, thus, no longer subject to its regulations. The petition should contain information on the biology of the crop species, the transformation system, the introduced genes and regulatory sequences, the genetic analysis (molecular characterization), the agronomic performance, and the environmental consequences of the unconfined release of the regulated article. After review of the petition document, USDA prepares a draft decision document and an environmental assessment document and solicits input from the public. If deregulated, the product can be imported, shipped, and planted without permit or notification and allows for product commercialization pending input from FDA and EPA, if required based on the introduced trait.

FDA. As stated in their 1992 policy document, FDA has a voluntary assessment program that allows developers of biotechnology-derived plants

to consult with FDA to ensure that the agency has no questions regarding the food and feed safety of the biotech plant or its derived products. The consultation process may involve early discussions to determine the type of data needed for a particular product. In general, the agency requests information on the following: name and use of the crop, the inserted genetic material, the resulting phenotype, the expressed protein(s), the potential allergenicity and toxicity of the introduced protein(s), and the nutritional composition of the resulting product. Following a review of the data, FDA issues a memorandum stating that the consultation is complete and agency has no further questions. To date, all of the biotech plant products that have been commercialized have gone through the FDA consultation process.

EPA. A biotechnology-derived product with a pesticidal trait (e.g., the trait is intended to prevent, repel, or mitigate a pest) is referred to as a plant-incorporated protectant (PIP) by the EPA. For such products, EPA requires a registration for sale and distribution of the PIP and a tolerance or exemption from the requirement of a tolerance to allow the PIP to be used in food. EPA requires the registrant to submit data on the following: product characterization such as protein expression, mammalian toxicity, gene flow, nontarget effects, and environmental fate. For insecticidal traits, EPA requires the submission of a plan to delay development of resistance to the PIP. Following commercialization, EPA may require additional data and impose reporting obligations to ensure effective insect resistance management.

2.9.4 International regulations

Many countries have regulations for the importation, testing, and commercialization of biotechnology-derived plants. The specific requirements vary for each country depending on the specific regulatory action requested, such as approval for importation and/or production. In general, all regulating countries require specific data to be submitted to address the food, feed, and environmental safety of biotech products that would be coming into the country. An excellent account of legislation and regulations related to the release of GM crops in various countries has been provided by Nap *et al.* (2003).

3. FUTURE PERSPECTIVES

The first reports on cotton transformation were published in 1987, some 20 years ago. Since its introduction to the US farmers in 1996, cotton has been the most widely planted GM crop around the world. However, the current commercial GM varieties carry only the input traits benefiting largely the cotton growers. Of course, the associated environmental benefits have been significant. The research studies and patents described in this chapter show the efforts being made to engineer a number of useful output traits into cotton. As discussed earlier, strength, fineness, length, and uniformity are not the only desired fiber characteristics, it will also be necessary to incorporate properties such as wrinkle resistance, shrinkage resistance, color retention, flame resistance, etc. for this natural fiber to effectively compete against petroleum-based, man-made fibers. It may be possible to achieve these goals through "Rational Fiber Design" by integrating plant biotechnology with textile chemistry to create value-added fibers for existing and new applications (Cantrell, 2005). As new genes become available from cotton and other organisms and as the genetic modification technologies are refined and improved, it will become possible to incorporate additional input and output traits into this important crop to benefit growers, consumers, and the environment.

ACKNOWLEDGMENTS

Research in the laboratory of senior author has been supported by funds from Texas Cotton Biotechnology Initiative (TxCOT), Cotton Incorporated, Texas Higher Education Coordinating Board (Advanced Research Program), Texas Food & Fibers Commission, and Texas Agricultural Experiment Station. The authors thank Ms. LeAnne M. Campbell for technical assistance.

1. INTRODUCTION

In January of 1983, the Miami Winter Symposia series hosted the conference on “Advances in Gene Technology: Molecular Genetics of Plants and Animals.” This conference would serve as a forum for unveiling one of the milestones in plant biology research—the introduction of a bacterial gene into a plant species. Two groups, one led by Mary-Dell Chilton and another led by Jeff Schell and Marc Von Montagu presented evidence that a bacterial gene for antibiotic resistance had been successfully integrated into the genome of tobacco plants. Since this seminal breakthrough, tobacco has become a widely used system for studies of gene function. It is the established system for plastid transformation; however, *Arabidopsis* has become the system of choice for nuclear gene integration due to the ease of transformation and a short generation cycle. This review summarizes the use of tobacco in dissecting plant biology concepts pertaining to the three important compartments of the cell that harbor genetic material within them. The chapter

begins with familiarizing the reader with the sequence of events that led to the development of tobacco regeneration and transformation systems. Next, the utility of the transgenic tobacco system is discussed, detailing the seminal research that enlightened a new understanding of gene function based on important *in planta* observations.

2. TRANSGENIC RESEARCH IN TOBACCO

2.1 Development of a Regeneration System and the Discovery of Cytokinins

Tobacco and carrot are the original model systems for plant tissue culture. While regeneration by somatic embryogenesis was first demonstrated with carrot cultures, the principles underlying regeneration via organogenesis were developed with tobacco. Tobacco tissue culture also has a historic role in hormone biology as the bioassay system used in the discovery of cytokinins in Folke Skoog’s lab at the University of Wisconsin-Madison. Cell division factors could not have been

discovered without a system in which their effects would be easily and unambiguously ascertained. Moreover, efficient regeneration is a prerequisite for transformation in plants. By virtue of its effective regeneration protocol, tobacco was the first plant to be transformed and has for many years been an important model plant for testing of transgenes.

2.1.1 Historical perspective: regeneration and the discovery of cytokinins

Early work on plant tissue culture focused on enticing cells to divide in culture. Important results were published by three researchers in the 1930s. Nobécourt (1938, 1939) and Gautheret (1939) in France reported on the maintenance of carrot callus cultures while White (1939a) in the United States concentrated his research on tobacco. It should be noted that White's tobacco cultures were derived from the hybrid *Nicotiana glauca* × *Nicotiana langsdorfii*, which is prone to form tumors *in planta*. White (1939a) showed that when these tumor tissues are placed *in vitro*, cell division could be maintained. Although this study only demonstrated the ability of naturally tumorous tissues to continue to divide *in vitro*, it did set the stage for further experiments using cultured tobacco tissues, eventually leading to the discovery of cytokinins and their role in organogenesis.

White (1939b) observed the occasional formation of shoots on tumorous tissues submerged in liquid medium. Skoog, whose research had focused on auxins, showed that the tumorous tissues contained high levels of β -indoleacetic acid (IAA) and that addition of IAA to the liquid culture medium suppressed the sporadic formation of buds in these tissues (Skoog, 1944). Roots appeared in a few of the cultures, always attached to the basal end of shoots (Skoog, 1944). This was the first demonstration of complete plantlet formation from callus tissue.

Subsequent research was performed with *Nicotiana tabacum* W38, a genetically normal tobacco variety as opposed to the tumorous plants employed by White, which would infrequently form callus, roots, and buds on stem segments in culture. It was also observed that callus formation could be stimulated and bud formation suppressed by exogenous auxin (Skoog and Tsui,

1948). Interestingly, addition of adenine sulfate could overcome this inhibitory effect of IAA but to accomplish that, very high adenine levels were required (Skoog and Tsui, 1948). These observations led the authors to conclude that "formation of roots, buds, or undifferentiated growth of tissues can be obtained by the application of different proportions of auxin and adenine to the medium". This was the first clear support for the concept that relative levels of growth factors control plant differentiation.

Pith tissue, which is rich in parenchyma but lacks vascular bundles, responded poorly to IAA but cell division was highly stimulated when natural extracts, such as coconut or malt extract, were added (Jablonski and Skoog, 1954). The biologically active fraction in yeast extract was isolated by Carlos Miller and found to be rich in purines (Skoog, 1994), which was consistent with the effects of adenine observed earlier. Further efforts by Miller in Skoog's lab focused on isolation of purines from natural substances and testing for their activity in tobacco cultures. The most potent substance was contained in autoclaved herring sperm DNA. The active compound was identified as N-furfuryladenine and its structure was subsequently confirmed by its chemical synthesis (Miller *et al.*, 1955a, b, 1956). The compound was given the name "kinetin" and was the first of a new class of plant growth regulators, named cytokinins for their ability to promote cytokinesis (Skoog *et al.*, 1965).

The discovery of kinetin led to an upsurge in plant tissue culture research. Skoog and Miller (1957) showed in the classical experiment that kinetin and auxin together could give rise to shoots, roots, or callus, depending on the concentrations and ratios between the two types of compounds. High kinetin with low IAA resulted in shoot formation, low kinetin with high IAA in root formation, and high concentrations of both in callus formation. Since that time, this principle was found to apply generally to regeneration of many plant genera through organogenesis. Application of plant growth regulators to control cell division and differentiation is used as an essential tool for plant biotechnology, from micropropagation to transformation.

Related research resulted in further refinements in tissue culture methods. To optimize callus growth, a chemically defined formulation was

devised based on analysis of ash from tobacco tissues (Murashige and Skoog, 1962). Further tests of organic nutrient requirements indicated that besides auxin and cytokinin, the only compounds necessary for tobacco tissue cultures, are sucrose, *myo*-inositol, and thiamine (Linsmaier and Skoog, 1965). This Murashige and Skoog (MS) mineral nutrient medium is still the most versatile and widely used plant tissue culture medium. Although many modified mineral media were developed after 1962 and given different names, they were often based on the MS medium. For more details on the development of the tobacco tissue culture system and the discovery of cytokinins, the reader is referred to Skoog (1994) and Armstrong (2002).

2.1.2 Development of a transformation system

Tobacco transformation was made possible by availability of a regeneration system as well as years of research on *Agrobacterium*, starting with the demonstration by Braun (1958) that tobacco crown gall tissues could grow in the absence of cytokinin and auxin even when *Agrobacterium* was eliminated from the tissues. This clearly showed that the tumor-inducing factors were maintained in the tissues even after many cell divisions. It should be noted that tobacco is an excellent host for *Agrobacterium*, forming large galls upon infection of stems, and has been used widely for crown gall research. An extensive treatise of *Agrobacterium*-based vector development is beyond the intention of this chapter and only a few of the important advances leading to tobacco transformation will be highlighted.

Two milestones on the road to transformation were the isolation of the *Agrobacterium* Ti plasmid (Zaenen *et al.*, 1974) and the demonstration that bacterial DNA was inserted in the DNA of host cells (Chilton *et al.*, 1977). They formed the basis for the identification of the essential genes inside as well as outside the transferred region and for the design of modified vectors for plant transformation. Also crucial to development of suitable gene vectors was incorporation of selectable markers, such as resistance to kanamycin (Bevan *et al.*, 1983; Fraley *et al.*, 1983; Herrera-Estrella *et al.*, 1983), which

made it possible to delete the tumor-forming genes. These and many other important contributions culminated in production of transformed tobacco and petunia plants that developed normally and formed progeny segregating for the transgene in a Mendelian fashion (De Block *et al.*, 1984; Horsch *et al.*, 1984). The procedures used to generate the transformants involved co-cultivation with protoplasts.

The tobacco protoplast transformation system was soon replaced by a much simpler system involving incubation of leaf discs with *Agrobacterium* (Horsch *et al.*, 1985, 1988). Tobacco leaf discs respond very well to cytokinin and auxin, just like the pith or callus tissues used by Skoog and Miller (1957). Shoots, roots, and callus can be obtained on appropriate combinations of the two hormones (Figure 1). Shoot formation at optimal growth regulator concentrations is very prolific, which is essential to efficient transformation. Moreover, callus formation is limited at concentrations used for shoot formation and thus the occurrence of somaclonal variants is minimized.

At about the same time as *Agrobacterium*-mediated systems were established, success was also reported on tobacco transformation by direct gene transfer with small plasmids (Paszkowski *et al.*, 1984). Direct gene transfer methods have,

Figure 1 Interaction between α -naphthaleneacetic acid (NAA) and N^6 -benzyladenine (BAP) in formation of roots, shoots, and callus from *N. tabacum* leaf discs

however, lower success rates and insertion into plant DNA is less precise, accompanied with more rearrangements. For practical purposes *Agrobacterium*-mediated transformation of leaf discs has remained the method of choice. An exception is transformation of chloroplasts, for which direct transformation is applied (discussed in Section 2.5).

2.1.3 The use of tobacco haploids to obtain lines homozygous for multiple inserts

N. tabacum is a disomic tetraploid, meiotically and genetically behaving like a diploid. As with most other species, there is an inherent problem when the objective is to generate transformed lines with multiple inserts (Smith *et al.*, 1994; Lee *et al.*, 2003). Although lines with more than one insert are often found after tobacco transformation, as indicated by ratios of 15:1, 63:1, etc., in the T₁, only one locus needs to be homozygous to render a T₂ completely resistant to the selective agent. Such lines are generally still segregating for the other insert loci and several further generations need to be characterized by extensive Southern analyses to identify completely homozygous lines for three or four insert loci.

Transformation of haploid tobacco followed by doubling of the chromosome number is an alternative and much quicker method for obtaining homozygous lines with multiple inserts. Haploid plants can be obtained through several routes (Nitsch and Nitsch, 1969; Burk *et al.*, 1979) and haploid materials are usually maintained as micropropagated shoots. Leaf discs from these shoots can be used for *Agrobacterium*-mediated transformation as described before for tetraploid tobacco, resulting in formation of transformed haploid shoots. The plants obtained after rooting of these shoots are normal but sterile. Interestingly, cultured midrib segments from fully expanded leaves can give rise to doubled haploid shoots whereas those from younger leaves only yield haploid shoots (Kasperbauer and Collins, 1972). Most of the plants (about 70%) obtained from the older leaves have doubled chromosome numbers and can be distinguished from haploids by their fertility. Progeny from each fertile plant should be homozygous for all transgenes.

The only disadvantage of this method resides in the fact that the number of independent inserts is initially unknown; however, Southern analyses after digestion with a restriction enzyme that does not cut the insert will quickly determine the number of independent inserts in each line. Overall, this procedure results in significant savings in time and effort.

2.2 Transgenic Tobacco and Light-Regulated Gene Expression

Not long after the introduction of transgenes into tobacco was published, several groups aggressively began functional characterization of promoter sequences *in planta*. Of particular interest were regulated promoters, especially those where activity was modulated by light. Light is essential for plant metabolism; therefore, it is little wonder that light also has significant roles in regulating plant growth and development. In this way plant form and composition are best adjusted to capture and utilize ambient light energy. Because of the clear importance of light in affecting plant biology, scientists have carefully studied the effects of specific wavelengths, intensities, and photoperiods on plant processes of agricultural or research interest. Before the widespread availability of molecular tools and techniques, hundreds if not thousands of careers were well spent characterizing the physiology associated with light developmental processes, the biochemical and spectral properties of regulatory pigments and the components that comprises transduction schema. While these scientists postulated the properties of various photosensors and signaling networks, their efforts preceded the availability, utility, and agility of *Arabidopsis* as a transformable genetic system.

In these cases, transgenic tobacco served as an important transitional system, owing to its ease of transformability and ability to produce ample resources for meaningful study in a short time. Transgenic tobacco was the structure–function workhorse, the best system to test various hypotheses of gene form and function throughout the 1980s and into the 1990s. With the advent of simple “floral dipping” (Clough and Bent, 1998) transformation of *Arabidopsis*, it then became possible to test constructs and heterologous

gene expression in this useful genetic system, and the tests in tobacco fell from favor. Still, tobacco's utility is realized in a contemporary context (Pierik *et al.*, 2004). The following pages present a historical account of experiments where tobacco served as a surrogate for gene constructs devised to dissect the roles of photoreceptors and their signaling mechanisms in regulating photomorphogenic phenomena.

2.2.1 Photoreceptors and photophysiology

The transgenic tobacco system was valuable in early characterization of photoreceptor contributions to plant growth and development. With *Arabidopsis* photomorphogenic mutants just being characterized, overexpression of photosensor constructs in a tobacco background allowed gain-of-function analyses that would allow description of receptor function. These were valuable because they could complement the many careful studies of action spectra or absorption spectra that described physiological phenomena and the receptors that guided them.

Phytochrome is a pigment that activates developmental, molecular, and biochemical processes upon absorption of red light (Quail, 2002; Casal and Yanovsky, 2005). The red light activated receptor is toggled off by far-red light. Under natural conditions the ratio of red to far-red is dictated by the position of the sun and the amount of atmosphere it travels through, so the red/far-red ratio is an accurate indicator of time and perhaps season. Far-red light is readily transmitted through, and reflected from plant tissue, therefore the red/far-red ratio is an important barometer of plant neighbor density or plant position within a canopy (Kim *et al.*, 2005; Vandenbussche *et al.*, 2005).

While the physiology and biochemistry of phytochromes was advanced in the early 1980s, little was known about the molecular mechanisms of *phy* signaling. In the absence of a simple transgenic genetic system like *Arabidopsis*, it was necessary to exploit the most agile systems of the day, in this case the recently defined transgenic tobacco system. More importantly, such a system would allow study of plant gene expression and characterize the regulation of genes and light-sensing mechanisms from monocotyledonous

species. Although critical to agriculture, efficient transformation of monocots has always lagged behind that of eudicots, such as tobacco. Because of this barrier, several early studies validated tobacco as an effective system to study regulation of light-regulated gene expression using constructs obtained from monocots (Lamppa *et al.*, 1985). Later, a rice type-I phytochrome (most likely phytochrome A by recent comparisons) was introduced into tobacco for studies of *phy* effects on circadian rhythms and plant growth. These studies were important because type-I phytochromes are typically absent from mature tissues and transgenic studies provided a platform to test the effects of type-I on various processes of biological interest. Tobacco plants containing the rice type-I *phy* cassette expressed the protein highly in leaves. The protein was abundant and associated correctly with its chromophore. Since there was ample evidence of expression, assembly, and photoactivation, the effect of the overexpressor was assessed in a transgenic context. When the mRNA levels of the rhythmically-expressed chlorophyll a/b binding protein (*cab*) gene were assessed, it became clear that *phy* overexpressors had greater amplitude of *cab* expression under free-run conditions, indicating a role for the receptor itself in maintenance of circadian rhythms. In a subsequent study, the effects of rice type-I *phy* overexpression on plant stature were evident, as *phy* overexpressors were short as seedlings and mature plants (Nagatani *et al.*, 1991). The change was attributed to a difference in cell elongation and not cell number.

A series of reports from Harry Smith's laboratory utilized transgenic tobacco to analyze the role of specific phytochrome receptors in mediating various plant responses to light. Transgenic lines of *N. tabacum* and *Nicotiana glauca* were constructed, overexpressing the phytochrome A (*PhyA*) gene from oat (*Avena sativa*) (Keller *et al.*, 1989). The initial characterizations showed that overexpressors generated a spectrally active chromoprotein of the proper size. The transgenic overexpressors exhibited dwarfish growth, a loss of apical dominance, and dark green leaves. The same plants were used by McCormac *et al.* (1992) to describe the relationship between far-red fluence rate and various plant responses. The study demonstrated that oat *phyA* was able to function

in a tobacco background, as transgenic seedlings possessed hypocotyls that were shorter than wild type when grown under a given fluence rate of far-red light. More importantly, wild type seedlings exhibited a loss of sensitivity to far-red whereas transgenic overexpressors did not, reinforcing a well-described theme of transcriptional down-regulation of *PhyA* upon illumination. Additional characterization of *Avena PhyA*-overexpressing tobacco seedlings was performed, measuring cotyledon angle in response to extremely low fluence pulses of red light (Casal *et al.*, 1994). The study confirmed that *phyA* is the photoreceptor mediating response to the most minor red irradiances.

These studies were expanded by assessment of *phy* degradation patterns in transformed cells in culture. Here McCormac *et al.* (1993) established liquid suspension cultures of tobacco cells overexpressing the oat *phyA*. The overexpressed *phyA* was the predominant form detected and was analyzed for degradation patterns following red or far-red irradiation, as well as for degradation dependence on chromophore association. *In vitro* changes in gene expression mirrored those induced *in vivo*. This work established and validated a single-cell system where phytochrome activation, signaling, response, and degradation could be further studied. Tobacco *PhyA* overexpressors also were used to study the effect of *PhyA* expression on germination. Tobacco and *Arabidopsis* differ in their spectral response to germination. Whereas *Arabidopsis* germination is induced with all wavelengths (Shinomura *et al.*, 1996), tobacco exhibits far-red induced inhibition of germination, much like that observed in Borthwick's classical experiments with "Grand Rapids" lettuce (Borthwick *et al.*, 1952). However, when harboring a *PhyA* transgene, seeds were less sensitive to the far-red block of germination (McCormac *et al.*, 1993).

The set of *phyA* studies in transgenic tobacco culminates with studies showing the effect of *phyA* overexpression on traits relevant to agriculture. Robson and Smith (1996) showed that strong overexpression of *phyA* results in a complete suppression of shade avoidance phenotypes, changes in architecture that render the plant elongate and hyponastic. High overexpression of *phyA* induced a proximity-conditional dwarf phenotype whereas some lines with lower expression levels

exhibited normal phenotypes in white light but shade avoidance defects when the red/far-red ratio was lowered (Schmitt *et al.*, 1995). In *PhyA* overexpressors, photosynthate was allocated away from stems in these plants, increasing assimilates in leaf tissue. The report concludes that overexpression of *PhyA* may be useful in other crops to increase harvest index. Similar neighbor insensitivity was noted by Casal and Sanchez (1994) when they carefully assessed the roles of red/far-red ratio on plant growth, concluding that overexpression of *phyA* would cause a lag in response to detection of neighbors. A study was designed to test if these effects had ecological ramifications. The adaptive plasticity hypothesis, the notion that environmentally induced changes in plant form and composition would actually have an effect on fitness, was tested using these same lines (Schmitt *et al.*, 1995). Analysis of *PhyA* overexpression and wild type lines showed that the ability to take on shade avoidance characters allowed plants to better compete, as evidenced by a greater dry mass in wild-type plants upon harvest. These findings support the adaptive plasticity hypothesis.

The studies of *Avena phyA* indicate a role for phytochrome in mediating responses to a shade environment, directed as a decrease in red/far-red ratio. Blue light and the gaseous hormone ethylene also have a role in regulating shade avoidance response (Pierik *et al.*, 2004). A report showed shade avoidance responses in transgenic tobacco bearing an overexpressed mutated copy of the *Etr1* gene, the gene encoding the ethylene receptor. These plants exhibit a dominant insensitivity to ethylene, which accumulated to high levels in dense stands of plants. The ethylene response was shown to be independent of the red/far-red ratio and was related to blue light fluence rates. This study demonstrates that shade avoidance symptoms are not simply affected by the red/far-red ratio and phytochrome activity.

Later, oat *phyA*, and *Arabidopsis* phytochrome B (*phyB*) and phytochrome C (*phyC*) were introduced independently to a tobacco background to probe the roles of individual phytochromes in various light responses (Halliday *et al.*, 1997). This study reiterated the respective sensitivities of *phyA* and *phyB* to far-red and red light, as well as demonstrated a role for *phyC* for the first time. Furthermore, this study showed the long-term

effects of *phy* overexpression on photoperiodic flowering. A cultivar normally insensitive to a night break on short days could be made sensitive with *phy* overexpression, and a cultivar normally exhibiting a delay in flowering after a night break showed an increased delay. This study provided a mechanistic complement to the plethora of photophysiological studies that tied phytochrome to regulation of photoperiodic flowering.

Studies in blue light signaling utilized the tobacco system as well. The aforementioned *Avena PhyA* overexpressor showed enhanced hypocotyl growth inhibition phenotypes under blue light (Casal and Sanchez, 1994). Transgenic tobacco systems were also used to characterize newly discovered blue light sensors. The *hy4 Arabidopsis* mutant was identified as a seedling with defects in its response to blue and white light (Koornneef *et al.*, 1980). The mutants possessed long hypocotyls and poorly developed cotyledons, indicating a major role for the HY4 protein in regulation of photomorphogenic development. Later, the *hy4* mutant would be found to encode a protein with homology to microbial photolyases (Ahmad and Cashmore, 1993), the light-activated flavoproteins that catalyze repair of thymidine dimers in DNA caused by ultraviolet damage. The photolyases absorb optimally in the blue and UV-A portion of the spectrum, correlating well with the wavebands that produce conspicuous phenotypes in the *hy4* mutant. These findings led to the compelling conclusion that *Hy4* encoded a flavin-based photoreceptor that regulated stem elongation during early light development. Although identified genetically in *Arabidopsis*, the transgenic tobacco system was used because of its ability to rapidly produce plants that could be used in further description of this new light sensor's function, as well as uncover structure–function relationships.

An important study by Lin *et al.* (1995) provided the overexpression data that complemented the *Arabidopsis* loss-of-function genetic studies. Transgenic tobacco seedlings were hypersensitive to UV-A, blue and green light treatment, growing with shorter stems than wild-type seedlings. *Hy4* overexpressing seedlings were not distinguishable from wild-type seedlings in darkness, red light, or far-red light. Here tobacco served as a rapid means to test the effect of a photoreceptor in a

heterologous system, showing that the receptor, as well as the transduction mechanism, is conserved between the two different species representing two different plant families.

2.2.2 Elucidating light signal transduction mechanisms

The use of transgenic tobacco provided a foundation to study the mechanism of phytochrome signal transduction. Studies of *Sinapis cab* promoter activity in transgenic tobacco demonstrated that the promoter's activity is dictated by the host context, as tobacco has contrasting sensitivity to phytochrome induction compared to mustard (Kretsch *et al.*, 1995). Initial studies of cell fractionation and immunocytochemical analyses provided evidence that PHYA and PHYB were localized to the nucleus upon light activation (Mosinger *et al.*, 1988; Sakamoto and Nagatani, 1996). These observations led to the exciting hypotheses repartitioning of the photoreceptor itself may constitute an important step in light signaling. However, cell fractionation studies were inconclusive due to the fact that phytochrome is a notoriously “sticky” protein, and may be improperly ascribed to a given location or condition. To bypass this problem, Kircher *et al.* (1999) studied the kinetics of photoreceptor repartitioning in transgenic tobacco. The authors created a fusion protein between phytochrome B and green fluorescent protein (GFP), allowing them to nondestructively track the movement of the protein through time following light treatment. The results indicate that the photoreceptor::GFP fusion is detected in the cytosol in dark-grown plants and then reapportioned to the nucleus following illumination, although PHYA and PHYB translocate with different kinetics and spectral sensitivities. The movement of PHYB to the nucleus is driven by red light, is far-red reversible, and has a low-fluence illumination threshold. Import of PHYA is much more light sensitive and occurred in response to both red and far-red light. These studies in tobacco illustrated that photoreceptor localization to, and removal from, the nucleus plays a central role in the regulation of gene expression by light, a theme that would form the foundation of further investigations.

2.2.3 Analyses of light-regulatory sequences

As useful as tobacco was to understand the physiology of photosensor function and the mechanisms of transduction, tobacco first served to establish a basis for light-regulated promoter studies. The first efforts appear in the literature from N.H. Chua's laboratory in the mid-1980s, where efforts centered upon the promoters of two light-regulated nuclear genes—*cab* and the small subunit of ribulose 1-5 biphosphate carboxylase/oxygenase (*rbcS*). These studies allowed a primary glimpse into the structural elements that coupled ambient light conditions to regulation of gene expression in plants. A study by Lamppa *et al.* (1985) indicated that the wheat *cab* genes were properly regulated in the heterologous tobacco system. Next Nagy *et al.* (1986) demonstrated the phytochrome reversibility of wheat *cab-1* in wheat, and showed that a 1.8 kb promoter fragment could faithfully execute phytochrome-mediated induction in transgenic tobacco. A follow-up study pared down the wheat *cab* regulatory regions to a 286 bp promoter region as that conferring phytochrome responsiveness, and showed that phytochrome did not affect transcript stability (Nagy *et al.*, 1987). A related study of the light-regulated 2.4 kb pea *rbcS* promoter showed that it could be properly regulated in the heterologous context, and that a significant deletion construct leaving only 352 bp was still sufficient to confer a phytochrome response. Kuhlemeier *et al.* (1989) used transgenic tobacco to characterize both positive and negative regulators of *rbcS* activation. The use of protein synthesis inhibitors in transgenic tobacco provided evidence indicating that light control of *cab* transcripts was due to labile factors (Lam *et al.*, 1989).

The utility of tobacco as a transgenic system was realized in the definition of sequence motifs that narrowed the analyses of large expanses of light-responsive promoters. One element with demonstrated light regulatory capacity is the GT-1 motif. A study by Lam and Chua (1990) utilized tobacco to illustrate that the GT-1 motif of the pea *rbcS* promoter could confer light-regulated activity to a normally constitutive promoter. Proper induction was seen in cells that contained chloroplasts, suggesting a signal from the organelle was necessary. While necessary, the GT-1 motif was not sufficient to confer

responsiveness (Cuozzo-Davis *et al.*, 1990). The GT-1 motif was later shown to be specifically part of a phytochrome responsive element (Gilmartin and Chua, 1990) and that the precise spacing between GT-1 motifs was critical for full activity (Gilmartin and Chua, 1990). A DNA binding activity designated 3AF1 bound to the light responsive promoter, but the elements bound did not confer light regulation to a constitutive promoter (Lam and Chua, 1990). Later transgenic suspension cultures would be used to illustrate that phytochrome induction of light-regulated genes could be induced by addition of calmodulin and inhibited by appropriate calmodulin inhibitors (Zhou *et al.*, 2001).

Analysis of regulatory regions of other light-responsive genes raised exciting new questions about the role of post-transcriptional processes in the maintenance of transcript abundance. In etiolated seedlings, the pea ferredoxin 1 (*Fed1*) gene exhibited unusual induction kinetics relative to *cab*, *rbcS*, and other light-regulated transcripts (Kaufman *et al.*, 1985, 1986). These findings prompted Elliott *et al.* (1989) to express the modular components of the pea *Fed1* gene in transgenic tobacco. Long (~2 kb) and short versions of the *Fed1* promoter were still active when driving a reporter gene, but no light regulation was observed. Conversely, the cauliflower mosaic virus 35S (CaMV 35S) promoter::*Fed1* transcript was strongly regulated by light, indicating that the regulatory sequences were downstream of the transcriptional start. Attachment of the *Fed1* sequence to a CaMV 35S-driven β -glucuronidase (GUS) construct conferred light regulation to the normally constitutive GUS transcript. Later analyses in transgenic tobacco showed that the upstream regulatory regions from pea were most active during the dark-light transition and that transcript regulation was more evident in the green tissues (Gallo-Meagher *et al.*, 1992).

To further dissect the regulatory mechanisms Petracek *et al.* (1997) studied accumulation of CaMV 35S-driven *Fed1* transcripts in response to the electron transport inhibitor 3-(3,4-dichlorophenyl)-1,1-dimethylurea (DCMU), as well as *Fed1* association with polysomes in light-grown and dark-adapted tissues. DCMU blocked accumulation of *Fed1* transcripts indicating an association with active photosynthesis. In light-grown tissue, *Fed1* transcripts were associated

with polyribosomes, whereas such relationships were not observed in darkness, in subthreshold illumination or after DCMU treatment. Later it would be shown that stability is associated with specific sequences in the 5'-UTR and coding region that would promote polysome association in light conditions, stabilizing the transcript (Dickey *et al.*, 1998). The stability could be broken with the introduction of termination codons into the coding region suggesting that active translation is required for optimal stability (Petracek *et al.*, 2000).

Regulation of another gene associated with photosynthesis was similarly studied using the transgenic tobacco system. A deletion series of the pea plastocyanin promoter (petE) was fused to GUS and introduced into transgenic tobacco (Pwee and Gray, 1993). The results described a host of positive and negative regulatory elements that occurred between -784 and +3 relative to the transcription start, and also required a plastidic signal. However, the light induction observed from truncated promoters never was as robust as that exhibited by the endogenes, leading the authors to conclude that other sequences located 3' to the transcription start may modulate gene expression. This hypothesis, initiated from a study in transgenic tobacco, revealed a post-transcriptional mechanism that would later be described in *Arabidopsis* with further resolution (Brown *et al.*, 2005).

Key enzymes of the phenylpropanoid pathway are regulated by light, and they too became targets for promoter analyses. A 1.1 kb fragment of the *Phaseolus vulgaris* phenylalanine lyase (PAL2) promoter was placed upstream of a GUS reporter and introduced into tobacco (Liang *et al.*, 1989). The resulting plants indicated that the promoter was active in specific tissues and could be regulated in a wound- and light-inducible manner. Similarly the promoter that drives the parsley *4CL-1* gene (encoding 4-coumarate:coenzyme A ligase) was placed upstream of the GUS reporter, and its activity was tested in a deletion series (Hauffe *et al.*, 1991). Transient assays in protoplasts isolated the regulatory regions to a 210 bp fragment, and activity was shown to be tissue specific in mature plants. The "G-box" motif is present in the promoters of many plant genes, and it was shown to be a functional part of the parsley *chalcone synthase* gene when activated by UV light (Kaulen *et al.*, 1986).

Although functional gene studies in tobacco have fallen from favor, it is important to remember that *Nicotiana* species still maintain many advantages over *Arabidopsis*. The large plants and organs are more amenable to biochemical techniques. Recently *Nicotiana benthamiana* and *N. tabacum* have been used for transient assays of transgenic protein function, as well as in vivo protein-protein interaction studies (Clemente, 2006). Plus, tobacco is a solanaceous crop, serving as a useful intermediate for translational genomics studies of light signaling in other solanaceous crop species, such as tomato. Although not a central system in the study of light-mediated processes, it is important for us to bear in mind the advantages of this system in elucidation of light-signaling mechanisms and their translation to relevant crop species.

2.3 Tobacco Transformation Studies for Biotic and Abiotic Stresses

Establishment of transgenic technology in tobacco ushered in an era of research to engineer resistance to various forms of stress. Crops are constantly being challenged by biotic and abiotic factors. Tobacco became a host to study and test the genes that could protect important crops in the future.

2.3.1 Biotic stress

2.3.1.1 Insect resistance

It has been well documented through pioneering research in tobacco that expression of *Bacillus thuringiensis* (*Bt*) endotoxin genes, as well as proteinase inhibitor (PI) genes, confer insect resistance. However, it must be noted that novel sources of resistance are continuing to be explored for future use in insect control.

Most Lepidoptera species are susceptible to the Cry 1 and Cry 2 insecticidal crystal proteins produced by *Bt*. The first studies to examine insect resistance following transfer of *Bt* genes were in tobacco in 1987 (Barton *et al.*, 1987; Vaeck *et al.*, 1987). These transgenic tobacco plants carried truncated versions of either *cry1Aa* or *cry1IAb*, respectively, and were resistant to the larvae of

Manduca sexta (L.). However, Cry protein levels were low (less than 0.001% of leaf soluble proteins) and this initially led to the use of synthetic *cry* genes whose expression levels were higher in plant cells. The codons of these bacterial *cry1Ab* and *cry1Ac* genes, as well as other features, were optimized for usage in plants and this raised the level of expression in transgenic tobacco (0.02–1% of leaf soluble proteins) (Perlak *et al.*, 1991). In these examples, the *cry* genes were driven by the constitutive CaMV 35S promoter. However, Williams *et al.* (1993) used the promoter from the pathogenesis-related *PR-1a* gene to control expression of *cry1Ab*. More recently, *cry2Aa2* was placed behind the promoter from the *Solanum tuberosum* leaf- and stem-specific (*ST-LS1*) gene to allow expression in green tissues of tobacco (Zaidi *et al.*, 2005). In this study, CRY2AS2 levels reached 0.21% of leaf soluble protein and plants were highly resistant to the larvae of *Heliothis virescens*. Another approach to increase *cry* gene expression (and improve transgene containment) has been to insert these genes into the tobacco chloroplast genome. Integration of a *cry1Ac* gene (McBride *et al.*, 1995), *cry2Aa2* (Kota *et al.*, 1999) and *cry11a5* (Reddy *et al.*, 2002) into the chloroplasts of tobacco led to high levels of expression (3–5% of leaf soluble proteins), and resistance to a number of economically important lepidopteran pests without deleterious effects on plant growth. De Cosa *et al.* (2001) expressed the *cry* operon in chloroplast transgenic tobacco resulting in accumulation of Cry protein to 46.1% of tsp with devastating effect on the lepidopteran pests. Recently, Chakrabarti *et al.* (2006) showed that expression of a truncated *cry9Aa2* in tobacco chloroplasts resulted in resistance to the potato tuber moth (PTM), *Phytorimacea operculella* as measured by leaf bioassays. Levels of CRY9AA2 were extremely high (10% of leaf soluble proteins); however, such high expression led to delayed development.

Other microbial genes also have proved useful. The *Agrobacterium tumefaciens* isopentenyl transferase (*ipt*) gene, which is important for cytokinin production, was introduced into tobacco under the control of the potato PI II gene promoter (Smigocki *et al.*, 1993). This wound-inducible system resulted in decreased feeding of *M. sexta* and increased mortality for the peach potato aphid, *Myzus persicae*. However, plant

development was negatively altered resulting in poor root systems and a reduction in chlorophyll levels.

Viral genes also have been introduced to curb insect feeding. Enhancin genes from *Trichoplusia ni* or *Helicoverpa armigera* baculoviruses encoding metalloproteases that breakdown mucin, which compromises the peritrophic membrane, were introduced into tobacco. *Trichoplusia ni* larvae allowed to feed directly on transgenic leaves showed reduced growth and development as well as increased mortality (Cao *et al.*, 2002). Long-term feeding studies using transgenic tobacco expressing the *Trichoplusia ni* baculovirus enhancin gene in artificial diets showed similar results with *Pseudaletia separata* and *Spodoptera exigua* larvae (Hayakawa *et al.*, 2004).

Plant PIs have been quite effective in reducing insect growth both *in vitro* and *in vivo*. The PIs are classified as inhibiting serine, cysteine, metallo or aspartyl proteases. The first PI gene shown to be effective against insects, cowpea trypsin inhibitor (CpTI), a serine PI, was introduced into tobacco in 1987 and displayed resistance to *M. sexta* and *H. virescens* (Hilder *et al.*, 1987). Since that time, numerous serine PI genes, including those expressing potato (*PPI-II*), tomato (*TI-II*), and sweet potato (*spTI-I*) PIs have been introduced into tobacco and shown to slow the growth of several species (Johnson *et al.*, 1989; McManus *et al.*, 1994; Yeh *et al.*, 1997). In 2000, three soybean genes (*KTi3*, *C-II*, and *PI-IV*) coding for serine PIs were introduced into tobacco (Marchetti *et al.*, 2000). In this study, 100% mortality was achieved for *S. littoralis* larvae fed on certain tobacco transgenic lines.

Lectins, a group of carbohydrate-binding proteins, have shown insecticidal properties. Tobacco expressing a pea lectin was toxic to *H. virescens* (Gatehouse *et al.*, 1992), while those expressing the snowdrop lectin (GNA) have displayed resistance to the peach potato aphid *M. persicae* (Hilder *et al.*, 1995). More recently, tobacco plants expressing the *Pinellia ternata* agglutinin transgene (*pta*) also reduced the growth of *M. persicae* (Yao *et al.*, 2003). Therefore, the *pta* gene could be used in conjunction with or pyramided with the snowdrop lectin gene (*gna*) to control aphids.

A CaMV 35S tobacco anionic peroxidase gene was able to provide broad-spectrum insect

resistance particularly to caterpillars, aphids, and whiteflies in both greenhouse (Dowd and Lagrimini, 1997) and field studies (Dowd and Lagrimini, 2006). However, the mode of action of the peroxidase is believed to be indirect and is not well understood.

Gamma-aminobutyrate (GABA), a nonprotein amino acid, accumulates in plants following various abiotic stresses. GABA is an inhibitory neurotransmitter that acts at insect neuromuscular junctions, and therefore may contribute to insect resistance. MacGregor *et al.* (2003) showed that tobacco transgenics expressing a glutamate decarboxylase complementary DNA (cDNA) and accumulating large amounts of GABA were not preferred by *H. virescens* compared to nontransgenics. Tryptamine is another neuroactive agent that results in insect antifeeding behavior. Transgenic tobacco plants expressing the tryptophan decarboxylase 1 gene leading to increased accumulation of tryptamine reduced the feeding and slowed the growth of *M. sexta* larvae (Gill *et al.*, 2003).

Caffeine was produced in tobacco via insertion of three coffee N-methyltransferase genes (Uefuji *et al.*, 2005). In preference studies, *S. litura* larvae fed on wild-type tobacco leaf discs rather than those of the transgenics. Therefore, caffeine may act as a feeding deterrent.

To date, genes derived from insects have conferred only low levels of insect resistance when expressed in tobacco. Chitin is a structural polysaccharide that is a component of the insect exoskeleton, as well as the peritrophic membrane, which separates food from midgut tissue. Genes coding for chitinases, normally produced by insects during moulting, have been cloned and introduced into plants for insect control. A *M. sexta* chitinase was expressed in transgenic tobacco, and when purified and fed to merchant grain beetle, *Oryzaephilus mercator*, resulted in toxicity (Wang *et al.*, 1996). A chitinase cDNA from *M. sexta*, introduced into tobacco, reduced feeding damage and growth of *H. virescens* larvae, but not of *M. sexta* larvae (Ding *et al.*, 1998). A synthetic gene containing multiple copies of the trypsin modulating and oostatic factor (TMOF) from *Aedes aegypti* (Aea-TMOF) was introduced into tobacco (Tortiglione *et al.*, 2002). *H. virescens* larvae fed with transgenic leaves expressing this gene showed a reduction in growth compared to

those fed with control plants. These genes may be more effective when used in conjunction with other control strategies.

Genes from animals also affect insectivory. Expression of a bovine spleen trypsin inhibitor (SI) gene in transgenic tobacco leaves was effective in decreasing both survival and growth of *H. armigera* larvae (Christeller *et al.*, 2002). When expressed at high levels, both biotin-binding proteins conferred a high level of insect resistance on transformed tobacco plants to larval PTM, *P. operculella* (Zeller) (fam. Gelechiidae), and on apple plants to larvae of the lightbrown apple moth (LBAM), *Epiphyas postvittana* (Walker) (fam. Tortricidae). More than 90% of PTM larvae died on tobacco plants expressing either avidin or streptavidin genes within nine days of inoculation (Marwick *et al.*, 2003).

The venom toxin, ω -ACTX-Hv1a (Hvt), from the Australian funnel web spider (*Hadronyche versuta*), acts as a calcium channel antagonist. Transgenic tobacco expressing Hvt were effectively protected with 100% mortality of *H. armigera* and *S. littoralis* larvae (Khan *et al.*, 2006).

2.3.1.2 Virus—pathogen- and nonpathogen-derived resistance

There are two main approaches to engineering plants for viral resistance. One approach is pathogen-derived resistance (PDR) where a portion or a complete viral gene is inserted into the plant conferring resistance. This was first demonstrated in transgenic tobacco plants containing the coat protein (CP) gene of tobacco mosaic virus (TMV) (Powell-Abel *et al.*, 1986). PDR has been studied and used extensively for a wide variety of viral genes, viruses, and hosts since that seminal report (see Dasgupta *et al.*, 2003 for review). Likewise, tobacco transgenics were used in the discovery that post-transcriptional gene silencing (PTGS) was the result of a diffusible signal. When viral RNA is the elicitor or target of PTGS, the mechanism is referred to as virus-induced gene silencing (VIGS) (see Robertson, 2004 for review). Transgenic tobacco studies (particularly using *N. benthamiana*) have been used extensively to understand the RNA silencing mechanisms at work in VIGS. The other approach

is nonpathogen-derived resistance that uses host resistance genes to confer virus resistance. Once again, tobacco has been a model organism to understand the resistance mechanisms and to generate transgenic virus resistant plants. The classic example is the tobacco N gene that provides resistance to TMV. It is a disease resistance gene (R) member of the toll-interleukin (TIR)-leucine-rich repeat (LRR) family.

2.3.1.3 Fungi—pathogenesis-related proteins

There are five families of PR proteins (PR-1 to PR-5) that have members displaying antifungal activity. In the first report of fungus-resistant transgenic plants, Broglie *et al.* (1991) expressed a bean chitinase gene in tobacco as well as in *Brassica napus* that displayed resistance to *Rhizoctonia solani*. Since that time, transgenic tobacco has been used in numerous studies to examine the antifungal effect of various PR-proteins expressed alone or in combination (e.g., Broglie *et al.*, 1991; Alexander *et al.*, 1993; Nielsen *et al.*, 1993; Vierheilig *et al.*, 1993; Liu *et al.*, 1994; Zhu *et al.*, 1994; Velazhahan and Muthukrishnan, 2003).

2.3.1.4 Bacteria

Magainin is one of the earliest reported antimicrobial peptides isolated from skin secretions of the African clawed frog *Xenopus laevis* and is thought to function as a natural defense mechanism against infection. The engineered magainin analog peptide, *Myp30*, was found to inhibit spore germination of the oomycete, *Peronospora tabacina* (Adam) *in vitro*, and the growth of a bacterial pathogen *Erwinia carotovora* subsp. *carotovora* (Jones). Transgenic tobacco (*N. tabacum* L.) plants expressing *Myp30* were evaluated for resistance to these pathogens. The expression of the peptide only to an extracellular location resulted in significant reduction in sporulation and lesion size due to *P. tabacina* infection. A significant increase in resistance to the bacterial pathogen was also observed regardless of the targeting location of the peptide (Li *et al.*, 2001).

2.3.2 Abiotic stress

Plant growth and productivity are greatly influenced by environmental conditions such as drought, cold, and salinity, which lead to water stress. Different kinds of stresses often trigger similar responses in plants as a result of cellular dehydration, which causes osmotic stress. In addition, the production of reactive oxygen species increases damage to cellular structures and impacts metabolism. Many stress-associated genes have been identified, including those involved in osmolyte biosynthesis, fatty acid metabolism, free radical detoxification, and signal transduction as well as molecular chaperones, ion and water transporters, and transcription factors. Tobacco transformation has played an important part in studies to evaluate the roles of these genes in stress tolerance.

To date, most studies have looked at constitutive overexpression of stress-related proteins using the CaMV 35S promoter. While this strategy allows elucidation of protein function with relative ease, it results in transgene expression in all parts of the plant at all developmental stages, which may have undesirable consequences for plant growth (Holmström *et al.*, 1996; Kumria and Rajam, 2002; Kasuga *et al.*, 2004). The use of stress-inducible promoters has demonstrated the potential to more effectively transfer genes or pathways for stress tolerance into other important plant species (Nelson *et al.*, 1998; Kasuga *et al.*, 2004; Khodakovskaya *et al.*, 2006). Expression of foreign proteins has also been controlled by the addition of targeting sequences (Shen *et al.*, 1997; Nuccio *et al.*, 1998).

2.3.2.1 Biosynthesis of osmolytes and osmoprotectants

Tobacco has provided a good model system for understanding the role of compatible solutes in osmotic stress. In response to a variety of stresses, compatible solutes accumulate in cells at high concentrations, facilitating the retention of water, and thereby stabilizing the structure of macromolecules, without interfering with cytoplasmic functions. Introduction of novel pathways for the biosynthesis of compatible solutes in tobacco has resulted in increased

stress tolerance of transgenic plants. Common nontoxic solutes include quaternary ammonium compounds, such as glycine betaine, amino acids, amino acid derivatives, sugars, and sugar alcohols.

2.3.2.2 Quaternary ammonium compounds—glycine betaine

Glycine betaine (GlyBet) is a quaternary ammonium compound occurring naturally in a variety of plants, animals, and microorganisms (Rhodes and Hanson, 1993). It is a very efficient compatible solute that accumulates in response to stress conditions. Transgenic approaches in tobacco and other higher plants that do not normally accumulate GlyBet have provided evidence for the physiological role of this osmoprotectant. GlyBet is synthesized in higher plants by the two-step oxidation of choline, catalyzed by a ferredoxin-dependent choline monooxygenase (CMO) and a NAD⁺-dependent betaine aldehyde dehydrogenase (BADH) (Rhodes and Hanson, 1993). In mammalian cells and *Escherichia coli*, GlyBet is synthesized by another two-step reaction involving a NAD⁺-dependent choline dehydrogenase (CDH) in combination with BADH (Landfald and Strøm, 1986). By contrast, the soil bacterium *Arthrobacter* is able to synthesize GlyBet directly from choline in a one-step reaction catalyzed by choline oxidase (COD) (Ikuta *et al.*, 1977).

Tobacco has been used extensively as a model for the introduction of GlyBet synthesis into a nonaccumulator. Engineering GlyBet synthesis in tobacco has been achieved by changing the CMO/BADH pathway, the CDH/BADH pathway, or the COD pathway (Sakamoto and Murata, 2000). Transfer of the CMO/BADH pathway from natural GlyBet accumulators to tobacco was attempted by introduction of a BADH cDNA from either spinach (*Spinacia oleracea*) or sugarbeet (*Beta vulgaris*) under control of the CaMV 35S promoter (Rathinasabapathi *et al.*, 1994). BADH was targeted to the chloroplasts of transgenic plants and levels of the enzyme were similar to those in spinach following salt stress. Transgenic plants accumulated GlyBet to high levels, but only in the presence of the exogenously supplied precursor betaine aldehyde, demonstrating that increased

expression of BADH alone was not sufficient for GlyBet synthesis in tobacco (Rathinasabapathi *et al.*, 1994). High levels of BADH expression were also achieved following transformation of tobacco with barley (*Hordeum vulgare*) BADH cDNA (Ishitani *et al.*, 1995). GlyBet accumulation was not reported; however, BADH transcripts accumulated in a stress-responsive manner. Li *et al.* (2003) introduced BADH from the halophyte *Suaeda liaotungensis* into tobacco, under control of the CaMV 35S promoter. Levels of GlyBet were much lower in transgenic plants than in *S. liaotungensis*, which accumulates GlyBet to high levels. Despite not accumulating GlyBet to physiologically relevant levels, some transgenic plants survived on media containing 200 mM NaCl and suffered less membrane damage than wild-type plants (Li *et al.*, 2003). Expression of GlyBet in tobacco has also been shown to increase tolerance to high temperature stress (45 °C) during seedling growth by maintaining the activation of Rubisco, enhancing photosynthesis (Yang *et al.*, 2005). These authors introduced the spinach BADH gene under control of the CaMV 35S promoter and transgenic plants were able to accumulate low levels of GlyBet, up to 4.6 µmol g⁻¹ fresh weight, mainly in chloroplasts.

Since non-GlyBet-accumulating plants show some BADH activity, a spinach CMO gene was introduced into tobacco under control of the CaMV 35S promoter, to investigate the potential for GlyBet production by engineering synthesis of this enzyme alone (Nuccio *et al.*, 1998). CMO was successfully targeted to the chloroplasts, but transgenic plants accumulated levels of GlyBet far below those of natural accumulators, possibly limited by the endogenous choline supply. In a similar approach, Huang *et al.* (2000) introduced the COD gene from *Arthrobacter pascens* into tobacco under control of the CaMV 35S promoter. Transgenic plants accumulated too little GlyBet to significantly affect osmoregulation, despite a moderate increase in salt tolerance (Huang *et al.*, 2000). In contrast to these studies, the COD gene from *Arthrobacter globiformis* (*codA*), targeted to the chloroplasts under control of the CaMV 35S promoter, conferred freezing tolerance (−2 °C for 24 h) on transgenic tobacco plants (Konstantinova *et al.*, 2002). Choline oxidase protein was detected in the homozygous line analyzed, although the expression level remained stable under nonstress or

stress conditions. Transgenic plants were also able to survive freezing stress under field conditions (Konstantinova *et al.*, 2002).

In an effort to remove the constraint placed by insufficient choline on GlyBet synthesis, Mcneil *et al.* (2001) employed a spinach cDNA encoding phosphoethanolamine *N*-methyltransferase (PEAMT), a key enzyme in choline biosynthesis. The PEAMT coding sequence was introduced under control of the strongly constitutive figwort mosaic virus 34S promoter, into tobacco plants already expressing spinach CMO and sugarbeet BADH. Transgenic plants contained up to 50-fold more free choline than control plants and GlyBet synthesis was enhanced up to 30-fold, without affecting plant growth (Mcneil *et al.*, 2001).

Attempts to engineer the bacterial GlyBet biosynthesis pathway into tobacco produced similar results to those targeting the plant pathway. Introduction of the second enzyme of the *E. coli* GlyBet pathway, *betB*, encoding BADH, was not sufficient for GlyBet production in tobacco (Holmström *et al.*, 1994). By comparison, the first enzyme of the *E. coli* GlyBet pathway, *betA*, encoding CDH, under control of the *Arabidopsis RbcS1A* promoter allowed GlyBet accumulation in transgenic tobacco plants (Holmström *et al.*, 2000). Plants expressing *betA* had enhanced salt tolerance, measured as reduction in fresh weight, compared to controls (Lilius *et al.*, 1996; Holmström *et al.*, 2000), and also showed greater resistance to photoinhibition under salt stress and low temperature conditions (Holmström *et al.*, 2000). When transgenic tobacco plants expressing *betA* were crossed with those expressing *betB*, effectively completing the biosynthesis pathway, GlyBet accumulation was two- to threefold higher than in plants only producing CDH (Holmström *et al.*, 2000). Transgenic lines producing both CDH and BADH, however, did not appear to have improved stress tolerance over those producing CDH alone.

2.3.2.3 Amino acids—proline

Proline accumulates to very high levels in plants under stress, protecting them against osmotic and oxidative stresses. In *E. coli*, proline biosynthesis from glutamate is controlled by a three-gene operon, *proB* (γ -glutamyl kinase),

proA (glutamic γ -semialdehyde dehydrogenase), and *proC* (Δ^1 -pyrroline-5-carboxylate reductase); however, in plants, proline can be synthesized directly from glutamate under stress conditions by Δ^1 -pyrroline-5-carboxylate synthetase (P5CS) (Delauney and Verma, 1993). An alternative proline biosynthesis pathway exists in plants, involving transamination of ornithine, catalyzed by ornithine- δ -aminotransferase (δ -OAT), to two possible intermediates, both of which can be reduced to proline. Engineering the proline biosynthesis pathway in tobacco has demonstrated that overproduction of proline in plants can confer increased tolerance to osmotic stress.

Kavi Kishor *et al.* (1995) introduced the mothbean (*Vigna aconitifolia*) P5CS gene into tobacco under control of the CaMV 35S promoter. Transgenic plants produced high levels of P5CS and synthesized 10- to 18-fold more proline (830 to 1590 $\mu\text{g g}^{-1}$ fresh weight) than control plants. Osmotic potential was maintained in leaf cells of transgenic plants and wilting was delayed under drought treatment, likely due to constitutive levels of proline (Kavi Kishor *et al.*, 1995). Transgenic plants also showed enhanced biomass and flower development under salt stress conditions (Kavi Kishor *et al.*, 1995). Under nonstress conditions, Konstantinova *et al.* (2002) observed only a threefold higher proline content compared to wild-type plants in tobacco lines transformed with the same mothbean P5CS gene. This level increased to 15-fold, however, during chilling and freezing stresses (-2°C for 24 h) (Konstantinova *et al.*, 2002). The same authors also introduced a P5CS gene from *Arabidopsis* into tobacco. There was no difference in proline content between these transformed lines and wild-type plants under normal conditions, but proline content increased five- to eightfold during chilling and freezing stresses (Konstantinova *et al.*, 2002). Plants harboring either P5CS gene were also able to survive freezing stress under field conditions (Konstantinova *et al.*, 2002). Tobacco plants engineered to express enzymes from the *E. coli* proline biosynthesis pathway are able to accumulate similar levels of proline under salt-stress conditions (Sokhansanj *et al.*, 2006).

Since P5CS is under feedback inhibition by proline, which may be lost under stress conditions, Hong *et al.* (2000) compared proline levels in transgenic tobacco plants expressing a wild-type

mothbean P5CS enzyme and a mutated form, whose feedback inhibition was removed, both under control of the CaMV 35S promoter. Under nonstress conditions, plants expressing the mutated P5CS enzyme accumulated twofold more proline than plants expressing the wild-type P5CS and had higher germination rates on media containing 200 mM NaCl. In addition, higher proline levels were associated with lower malondialdehyde (MDA) levels, a major cytotoxic product of lipid peroxidation used as an indicator of free radical production (Hong *et al.*, 2000).

To investigate the possibility of increasing osmotolerance in plants by manipulating the ornithine-dependent proline biosynthesis pathway, Roosens *et al.* (2002) introduced the *Arabidopsis* ornithine- δ -amino transferase (δ -OAT) cDNA into tobacco, under control of the CaMV 35S promoter. Transgenic plants overexpressing δ -OAT synthesized approximately threefold more proline than control plants and had increased biomass and germination frequency under osmotic stress conditions. In another alternative strategy to increase proline biosynthesis, Yonamine *et al.* (2004) introduced the tobacco *NtHAL3a* gene, involved in the coenzyme A biosynthetic pathway, into cultured tobacco BY2 cells under control of the CaMV 35S promoter. Transgenic plants contained approximately four- to fivefold more proline under nonstressed and salt-stressed conditions and showed improved tolerance to 100 mM and 140 mM NaCl (Yonamine *et al.*, 2004). Kolodyazhnaya *et al.* (2006) introduced an antisense suppressor of proline dehydrogenase from *Arabidopsis* into tobacco, leading to transgenic plants with increased proline content and elevated salt tolerance.

2.3.2.4 Amino acid derivatives—polyamines

Polyamines (PAs) are nitrogenous cellular compounds, formed by the decarboxylation of amino acids, which accumulate under a variety of abiotic and oxidative stress conditions. Examples include putrescine, spermidine, and spermine. The role of PAs in plants has been studied by overexpression of S-adenosylmethionine decarboxylase (*samdc*), a key enzyme in spermidine and spermine biosynthesis, in tobacco. Transgenic tobacco plants expressing a carnation (*Dianthus*

caryophyllus L.) *samdc* cDNA under control of the CaMV 35S promoter accumulated 2.2–3.1 times more soluble total PAs than wild-type plants (Wi *et al.*, 2006). Transgenic plants had an increased number and weight of seeds, increased net photosynthetic weight, and suffered less chlorophyll degradation after salt, cold, acidic stress, and abscisic acid (ABA) treatment. In addition, transcription of antioxidant enzymes was induced more significantly in transgenic plants than controls, following stress treatment (Wi *et al.*, 2006). Increased PA biosynthesis in transgenic tobacco was also achieved by introduction of a human *samdc* gene under control of the CaMV 35S promoter (Waie and Rajam, 2003). Transgenic plants had increased spermidine and putrescine levels and exhibited tolerance to salt stress (250 mM NaCl) and PEG-induced drought stress. Kumria and Rajam (2002) expressed the mouse putrescine synthesis gene ornithine decarboxylase (ODC) in tobacco under control of the CaMV 35S promoter to up-regulate PA metabolism. Transgenic plants had higher mouse ODC activity, but reduced activity of plant ODC and the alternative putrescine synthesis gene arginine decarboxylase (ADC). PA levels were two- to threefold higher in transgenic plants compared to controls and plants were more tolerant to salt stress (300 mM NaCl) (Kumria and Rajam, 2002).

PAs share a common precursor, S-adenosylmethionine (SAM), with ethylene, resulting in metabolic competition between ethylene and PA biosynthesis. Antisense expression of ethylene biosynthetic genes is expected to shift the competition for the SAM precursor in favor of PA biosynthesis. Wi and Park (2002) introduced antisense constructs of carnation cDNAs encoding 1-aminocyclopropane-1-carboxylic acid (ACC) synthase or ACC oxidase into tobacco. Transgenic lines had higher PA contents and increased number and weight of seeds, in addition to reduced chlorophyll loss following oxidative stress, high salinity, acid conditions, or ABA treatment (Wi and Park, 2002).

2.3.2.5 Sugars and sugar alcohols

Compounds related to sugar metabolism also accumulate in plants during responses to water

stress and osmotic adjustment. These include sucrose, trehalose, fructans, mannitol, and D-ononitol. The role of these osmolytes in protecting against abiotic stress has been investigated by engineering tobacco with enzymes in their biosynthetic pathways.

Sucrose and hexose concentrations in the cytoplasm of plant leaf cells can be increased by inhibition of sugar transportation to the sink organ. Transgenic tobacco plants expressing an apoplastic yeast invertase maintained constant photosynthetic activity and higher turgor pressure under 300 mM salt stress, whereas wild-type plants showed marked photoinhibition and a greater increase in osmotic pressure (Fukushima *et al.*, 2001).

The nonreducing disaccharide trehalose protects biomolecules from environmental stress in many microorganisms. Most plant species, however, do not appear to accumulate trehalose to detectable levels. Increasing trehalose concentrations in plants could therefore enhance drought and salinity tolerance (Penna, 2003). Trehalose is produced from UDP-glucose and glucose-6-phosphate, via trehalose-6-phosphate, catalyzed by the enzymes trehalose-6-phosphate synthetase and trehalose-6-phosphate phosphatase (Goddijn and Van Dun, 1999). Transgenic tobacco plants expressing the yeast trehalose-6-phosphate synthetase (*TPS1*) gene under control of the Rubisco small subunit (*rbcS*) promoter accumulated low concentrations of trehalose, ranging from 0.08% to 0.32% of the dry weight, in leaves and roots (Holmström *et al.*, 1996). Plants exhibited significant growth retardation and detached leaves showed reduced water loss compared to controls, when subject to air-drying. In a similar experiment, transgenic tobacco plants expressing the yeast trehalose-6-phosphate synthetase (*TPS1*) gene under control of the CaMV 35S promoter accumulated trehalose up to 0.17 mg g⁻¹ fresh weight in leaves and showed increased drought tolerance (Romero *et al.*, 1997).

These plants also exhibited phenotypic changes including stunted growth and lancet-shaped leaves, as well as reduced sucrose content. In this case, water loss from detached leaves was not significantly affected by trehalose accumulation. Given also that trehalose concentrations in transgenic plants were too low for a conventional osmoprotectant

effect, these authors suggested that sugar synthesis had resulted in altered sugar metabolism (Romero *et al.*, 1997). Recently, a trehalose-6-phosphate gene from *Arabidopsis* (*AtTPS1*) was introduced into tobacco under control of the CaMV 35S promoter (Almeida *et al.*, 2005). Transgenic lines displayed higher germination frequencies on media containing 0.5 M mannitol or 0.2 M NaCl or under temperature stress at 15 °C or 35 °C. In accordance with earlier experiments, water loss in transgenic plants or detached leaves did not vary significantly between transgenic and wild-type plants (Almeida *et al.*, 2005).

Overexpression of the *E. coli* trehalose-6-phosphate synthetase (*otsA*) and trehalose-6-phosphate phosphatase (*otsB*) genes in tobacco plants also enhanced trehalose synthesis (0.11 mg g⁻¹ fresh weight) with concomitant changes in leaf morphology (Goddijn *et al.*, 1997). Despite the low-level accumulation of trehalose in transgenic tobacco expressing both *otsA* and *otsB*, an increase in dry mass and improved photosynthesis under drought stress was observed (Pilon-Smits *et al.*, 1998). The low levels of trehalose accumulation observed in transgenic plants overexpressing genes of the trehalose biosynthetic pathway may result from the activity of an endogenous trehalase enzyme, which breaks down trehalose to glucose (Goddijn *et al.*, 1997). When the potent trehalase inhibitor validamycin A was added to transgenic plants *in vitro* or growing hydroponically, trehalose accumulation increased up to 0.41 mg g⁻¹ fresh weight in tobacco leaves (Goddijn *et al.*, 1997).

Fructans are soluble, polymers of fructose, used as storage sugars in many plants, but not tobacco. It has been suggested that, due to their solubility, fructans may also play a role in osmotic adjustment (Pilon-Smits *et al.*, 1995). The *SacB* gene encoding levansucrase from *Bacillus subtilis*, fused to the carboxypeptidase Y vacuolar sorting signal from yeast, was introduced into tobacco under control of the CaMV 35S promoter to produce transgenic plants that accumulate bacterial fructans (Pilon-Smits *et al.*, 1995). Fructan-producing plants performed significantly better under polyethylene-glycol-mediated drought stress, exhibiting 55% higher growth rates than wild-type plants resulting in 33% more fresh weight and 59% more dry weight (Pilon-Smits *et al.*, 1995). This difference in weight was most pronounced in the roots. In addition

to polyethylene-glycol-mediated drought stress, Konstantinova *et al.* (2002) found that tobacco plants carrying the *SacB* gene were able to recover from freezing stress (-2°C for 24 h), whereas wild-type tobacco plants were not. Plant survival under freezing field conditions was also increased, allowing earlier planting. Fructan accumulation increased in the transgenic line during freezing stress and decreased after recovery (Konstantinova *et al.*, 2002).

The sugar alcohol mannitol occurs widely in plants and animals, but is not normally synthesized in tobacco. Tarczynski *et al.* (1992) overexpressed the *E. coli* mannitol-1-phosphate dehydrogenase (*mtlD*) gene in tobacco, under control of the CaMV 35S promoter, resulting in biosynthesis of mannitol. Mannitol concentrations were greater than $6\text{ }\mu\text{mol g}^{-1}$ fresh weight in the leaves and roots of some transformed plants (Tarczynski *et al.*, 1992). Transgenic plants showed increased tolerance to prolonged high salt conditions (30 days of 250 mM NaCl) (Tarczynski *et al.*, 1993). Fresh weight loss in plants from *mtlD* lines was less than in control lines and transgenic plants increased in height by an average of 80% compared to 22% in control plants. However, since plants containing mannitol often produced new roots and leaves, the relative increases in fresh weight and height in these plants are likely due to new growth rather than a reallocation of resources (Tarczynski *et al.*, 1993). Karakas *et al.* (1997) introduced the same *mtlD* cassette into tobacco and saw only marginal increases in dry mass under salt stress. Transgenic plants were 20–25% smaller than wild-type tobacco plants, but whereas salt stress decreased the dry weight of wild-type plants by 44%, transgenic plants suffered no reduction in dry weight. Since mannitol was shown to be a relatively minor osmolyte in transgenic tobacco, the slower growth of transgenic plants and not the presence of mannitol *per se*, may have resulted in greater salt tolerance. Shen *et al.* (1997) targeted *mtlD* to the chloroplasts by addition of an aminoterminal transit peptide. Mannitol accumulated at concentrations ranging from 2.5 to $7\text{ }\mu\text{mol g}^{-1}$ fresh weight, with one line accumulating approximately 100 mM mannitol in chloroplasts. These plants had increased resistance to methyl-viologen-induced oxidative stress, as demonstrated by increased retention of chlorophyll in leaves following treatment (Shen

et al., 1997). The location of mannitol in chloroplasts appeared to increase the hydroxyl radical-scavenging capacity of cells, thereby reducing oxidative damage.

Transgenic tobacco plants with increased tolerance to salt and drought conditions were produced by introducing a *myo*-inositol *O*-methyltransferase (IMT1) cDNA from ice plant (*Mesembryanthemum crystallinum*) into tobacco under control of the CaMV 35S promoter (Sheveleva *et al.*, 1997). In the halophytic ice plant, IMT1 methylates *myo*-inositol to form D-ononitol, a cyclic polyol, in a stress-inducible manner, likely resulting in decreased osmotic potential in the cytoplasm and regulation of sodium accumulation in the vacuole (Nelson *et al.*, 1998). Transgenic tobacco plants accumulated D-ononitol in amounts exceeding $35\text{ }\mu\text{mol g}^{-1}$ fresh weight, experienced less inhibition of photosynthetic CO_2 fixation and recovered more quickly from salt or drought stress. One day after rewatering drought-stressed plants, photosynthesis had recovered 75%, compared to 57% in wild-type plants (Sheveleva *et al.*, 1997).

2.3.2.6 Ectoine

Ectoine is a tetrahydropyrimidine that functions as a compatible solute in halophilic bacteria, where it is synthesized from aspartic β -semialdehyde by three successive enzyme reactions. The three ectoine biosynthetic genes, *ectA*, *ectB*, and *ectC*, from *Halomonas elongate* were each placed under control of the CaMV 35S promoter and introduced together into tobacco cv. Bright Yellow 2 (BY2) cells (Nakayama *et al.*, 2000). Transgenic BY2 cells accumulated ectoine to low levels (14 to 79 nmol g^{-1} fresh weight) and displayed tolerance to hyperosmotic shock (620 mM mannitol or 500 mM NaCl for 20 min) (Nakayama *et al.*, 2000). The ectoine biosynthesis genes were used to create transgenic tobacco plants that accumulated ectoine under salt stress conditions (Moghaieb *et al.*, 2006). Transgenic plants showed less reduction in dry weight, photosynthetic rate, and impairment of stomatal conductance than wild-type plants, as well as increased Na^+ concentrations in leaves and roots and increased osmotic adjustment (Moghaieb *et al.*, 2006). Ectoine was suggested to improve maintenance of root function, so

that water is taken up consistently under saline conditions and to increase transpiration and protect Rubisco proteins from salt, thereby increasing photosynthetic rate (Moghaieb *et al.*, 2006).

2.3.3 Protective proteins

2.3.3.1 LEA and LEA-related proteins

Osmotic stress induces late embryogenesis-abundant (LEA) proteins in plant's vegetative tissues, a large and diverse group of stress-responsive proteins conferring dehydration tolerance (Bartels and Sunkar, 2005). Dehydrins are group-2 LEA proteins that respond to water stress in plants. Members of the LEA/dehydrin superfamily have been expressed in tobacco, to investigate their role in dehydration stress, including plant responses to freezing. Kaye *et al.* (1998) introduced cDNA sequences encoding the spinach CAP160 and CAP85 cold-acclimation proteins into tobacco, under control of the CaMV 35S promoter. Transgenic plants containing each sequence were crossed to obtain progeny expressing both proteins. The CAP160 sequence had very limited homology to the Arabidopsis rd29A and rd29B stress-regulated proteins and CAP160 mRNA expression was increased by low temperature and water stress (Kaye *et al.*, 1998). Whilst the temperature at which 50% of cells were killed by freezing stress did not vary between transgenic and wild-type tobacco, plants expressing the spinach proteins suffered slightly less electrolyte leakage, suggesting a small reduction in freeze damage (Kaye *et al.*, 1998). Citrus (Citrus unshiu Markov.) dehydrin (CuCOR19) cDNA was introduced into tobacco under control of the CaMV 35S promoter (Hara *et al.*, 2003). Transgenic plants suffered less electrolyte leakage than control plants following 3 h freezing stress at -4°C and also exhibited better seedling growth and earlier germination at 15°C . MDA content was lower in transgenic lines than control lines following freezing stress, indicating reduced lipid peroxidation (Hara *et al.*, 2003). The CuCOR19 protein prevented peroxidation of soybean liposomes *in vitro*, suggesting that this dehydrin may act as a radical scavenging protein, protecting plant membranes.

2.3.3.2 Osmotin

Osmotin is a protein involved in adaptation to low water potential, but not induced by osmotic shock in cultured tobacco cells (Singh *et al.*, 1989). Synthesis of mRNA encoding osmotin is either induced or stabilized by ABA, but accumulation of the protein is induced by adaptation to low water potentials via a post-translational control mechanism (Singh *et al.*, 1989). The osmotin gene was overexpressed in tobacco plants under control of the CaMV 35S promoter (Sokhansanj *et al.*, 2006). Transgenic plants were able to produce shoots on medium containing 320 mM NaCl and showed comparable chlorophyll *a* content to wild-type plants (Sokhansanj *et al.*, 2006).

2.3.3.3 Heat shock proteins

Maintenance of protein functional conformation and prevention of aggregation is important for cell survival following abiotic stress. Heat shock proteins (HSPs) are synthesized upon exposure to high temperature stress and assist in protein refolding under stress conditions (Wang *et al.*, 2004). Overexpression of HSPs in tobacco has been used to improve understanding of HSP function during temperature stress.

A tobacco class I cytosolic small HSP gene, *TLHS1*, which showed a strong molecular chaperone activity *in vitro*, was overexpressed in tobacco under control of the CaMV 35S promoter (Park and Hong, 2002). Transgenic plants were less affected by heat stress at 40°C for 4 h or 45°C for 1 h, as measured by almost two times higher cotyledon opening rate in transgenic compared to control plants. A mitochondrial small HSP (MT-sHSP) cDNA from tomato (*Lycopersicon esculentum*) was introduced into tobacco under control of the CaMV 35S promoter (Sanmiya *et al.*, 2004). Transgenic plants constitutively produced the MT-sHSP protein, accumulating higher levels after heat stress and were able to survive treatment at 48°C for 2 h, in contrast to wild-type plants. Transgenic tobacco plants, expressing tobacco HSP70 (*NtHSP70-1*) under control of the CaMV 35S promoter, produced significantly higher levels of HSP70 in leaves than control plants, under nonstress conditions (Cho and Hong, 2006). Three-week-old, HSP70

overexpressing seedlings were able to maintain leaf turgidity following 2 weeks drought stress, whereas control plants showed severe wilting and stress symptoms. Expression of the *CaERD15* (early responsive to dehydration) gene was considerably reduced in HSP70 overexpressing lines following drought stress, suggesting increased dehydration stress tolerance (Cho and Hong, 2006).

Alvim *et al.* (2001) transformed tobacco with the CaMV 35S promoter driving expression of the soybean (*Glycine max*) chaperone binding protein (BiP), a constitutively expressed HSP70 (HSC70) homolog and an important component of the endoplasmic reticulum stress response. Transgenic tobacco plants harboring a sense-orientation BiP gene displayed enhanced tolerance to the glycosylation inhibitor tunicamycin, which promotes the accumulation of unfolded proteins in the endoplasmic reticulum. Sense transgenic plants were able to maintain leaf turgidity under progressive dehydration stress, whereas antisense transgenic plants showed increased sensitivity to water stress (Alvim *et al.*, 2001). BiP may act to alleviate oxidative stress, since levels of the antioxidant enzyme superoxide dismutase (SOD) were increased in control and antisense plants, but not in sense transgenic plants (Alvim *et al.*, 2001).

2.3.3.4 Membrane damage—fatty acid metabolism genes

Membrane damage under cold stress may be dependent upon the degree of unsaturated fatty acids present in phosphatidyl-glycerol membranes. Chilling-sensitive plants possess a high degree of saturated fatty acids, whereas cold-tolerant plants contain a high proportion of unsaturated fatty acids. During acclimation to cold temperatures, desaturase enzymes increase the proportion of unsaturated fatty acids allowing membranes to remain fluid (Iba, 2002). Cold stress also increases production of free radicals leading to lipid peroxidation. This causes loss of unsaturated fatty acids, increase in membrane rigidity, and membrane degradation. Transgenic tobacco experiments have contributed to understanding the relationship between low temperature tolerance and membrane rearrangement and synthesis.

The effect of unsaturated membrane lipid levels on chilling tolerance was demonstrated by the

introduction of a cDNA encoding glycerol-3-phosphate acyltransferase from chilling-sensitive squash into tobacco, under control of the CaMV 35S promoter (Murata *et al.*, 1992; Moon *et al.*, 1995). The transgenic plants showed increased saturation of chloroplast thylakoid membrane lipids, resulting in a slightly decreased ability of leaves to recover from low-temperature photoinhibition. Ishizaki-Nishizawa *et al.* (1996) introduced a broad-specificity $\Delta 9$ desaturase gene (*des9*) from the cyanobacterium *Anacystis nidulans* into tobacco under control of the CaMV 35S promoter. This desaturase, which was targeted to plastids, introduces a *cis*-double bond at the $\Delta 9$ position of both 16 and 18 carbon-saturated fatty acids. Transgenic plants had reduced saturated fatty acid contents in most membrane lipids and displayed tolerance to prolonged chilling (11 days at 1 °C or 52 days at 10 °C).

Tobacco was transformed with an *Arabidopsis* chloroplast ω -3 fatty acid desaturase gene (*FAD7*) under control of the CaMV 35S promoter to produce plants with increased levels of trienoic (16:3 and 18:3) fatty acids (Kodama *et al.*, 1994). Transgenic plants displayed enhanced cold tolerance compared to wild-type plants, which showed inhibition of leaf growth after 7 days at 1 °C. Khodakovskaya *et al.* (2006) introduced the *FAD7* gene into tobacco under control of the cold-inducible *Arabidopsis cor15a* promoter. Compared to wild-type plants, transgenic plants showed greater survival under prolonged low temperature stress (44 days at 0.5, 2, or 3.5 °C), more stable levels of trienoic fatty acids and stability of chloroplast membrane ultrastructure (Khodakovskaya *et al.*, 2006). Conversely, transgenic tobacco lines in which the *FAD7* gene was silenced contained lower levels of trienoic fatty acids and were able to acclimate better to higher temperatures (45 days at 36 °C or 3 days at 47 °C) (Murakami *et al.*, 2000). Hamada *et al.* (1996) introduced a tobacco microsomal ω -3 fatty acid desaturase gene (*NtFad3*) in sense and antisense orientations under control of the CaMV 35S promoter. In one of the sense lines, the 18:3 content increased by about 1.5-fold in root tissues and 1.1-fold in leaf tissues, whereas in antisense lines, the 18:3 content was decreased to about 80% in root tissues and 70–80% in leaf tissues, compared to control plants (Hamada *et al.*, 1996). Recently transgenic tobacco plants were produced

that express the transcript of a double-stranded RNA (dsRNA) of the tobacco plastid ω -3 fatty acid desaturase gene *NtFAD7* (Hamada *et al.*, 2006). Compared to control plants, 16:3 and α -18:3 fatty acid contents decreased to less than 2.7% and 7.5–10.4%, respectively, in leaves of transgenic plants. Increased drought tolerance was observed in tobacco plants overexpressing cytosolic *B. napus* *FAD3* or plastidic *Arabidopsis* *FAD8* ω -3 fatty acid desaturase genes under control of the CaMV 35S promoter (Zhang *et al.*, 2005). Plants expressing *FAD3* showed a large increase in the ratio of linolenic (18:3) to linoleic (18:2) acids, whereas in *FAD8* expressing plants, this increase was smaller and mainly associated with plastidic lipids.

2.3.4 Ionic stress

2.3.4.1 Transporter proteins

Maintaining intracellular ion homeostasis is critical to cell survival, affecting enzyme activities and membrane potentials. Exposure to high salt environments imposes sodium toxicity in addition to osmotic stress. Plants employ three mechanisms to prevent excess Na^+ accumulation in cells (Zhu, 2003; Bartels and Sunkar, 2005). Na^+ transporters restrict the entry of Na^+ into cells; intracellular Na^+ is compartmentalized into the vacuole; plasma membrane Na^+/H^+ antiporters transport cytosolic Na^+ back into the external medium or the apoplast. Whilst many of the genes involved in ion homeostasis have been identified and their regulatory mechanisms elucidated in *Arabidopsis*, tobacco has provided a background to compare these genes with those of the halophyte *Thellungiella halophila*.

Gao *et al.* (2006) introduced vacuolar H^+ -pyrophosphatases (PPases) from *T. halophila* (*TsVP*) and *Arabidopsis* (*AVPI*) individually into tobacco, under control of the CaMV 35S promoter. These enzymes function to pump Na^+ into vacuoles. At 300 mM NaCl, transgenic plants had 60% greater dry weight than wild-type tobacco and higher viability of mesophyll protoplasts (Gao *et al.*, 2006). Transgenic lines expressing *TsVP* were able to accumulate 25% more solutes than wild-type plants under nonstress conditions and 20–32% more Na^+ under salt stress. Cell membrane damage and MDA content were

reduced in *TsVP*-expressing plants, suggesting that compartmentalization of Na^+ in vacuoles reduces its toxic effects on cells (Gao *et al.*, 2006). Salt tolerance in tobacco was also improved by overexpression of the *GhNHX1* cDNA, a putative tonoplast Na^+/H^+ antiporter from cotton (*Gossypium hirsutum*), under control of the CaMV 35S promoter (Wu *et al.*, 2004).

2.3.4.2 Calcineurin

Calcineurin (CaN) is a Ca^{2+} - and calmodulin-dependent protein phosphatase (PP2B) that is an integral intermediate of a salt stress transduction pathway in yeast effecting NaCl tolerance through regulation of Na^+ influx and efflux. A truncated form of the catalytic subunit and the regulatory subunit of yeast CaN were co-expressed in tobacco, under control of the CaMV 35S promoter, to reconstitute a constitutively active phosphatase *in vivo* (Pardo *et al.*, 1998). Transgenic lines exhibited increased tolerance to NaCl as seedlings *in vitro* or as plants in hydroponics. The protective effects of CaN in transgenic tobacco appeared to result from the preservation of root integrity during salt shock (Pardo *et al.*, 1998). These results provided evidence that modulation of a signal transduction pathway in plants could be used to improve stress tolerance.

2.3.4.3 Calcium binding protein

Pandey *et al.* (2002) produced transgenic tobacco plants expressing a novel calcium binding protein from *Entamoeba histolytica* (EhCaBP), under control of the CaMV 35S promoter. Seeds of transgenic plants showed enhanced germination rates under nonstress conditions and seedlings produced 20–37% more dry weight than wild-type plants. Transgenic seeds were also able to germinate and grow on 200 mM NaCl and produced 55–100% more dry weight compared to wild-type plants (Pandey *et al.*, 2002).

2.3.5 Oxidative stress—detoxification

Abiotic stress often leads to severe cellular damage in plants as a result of oxidative

stress. Antioxidant enzyme systems protect plant cells by either suppressing the production of, or by scavenging reactive oxygen intermediates (Mittler, 2002). Generation of transgenic tobacco plants overexpressing components of reactive oxygen-scavenging systems has been important in understanding how plants defend themselves against oxidative stress (Allen, 1995).

2.3.5.1 Reactive oxygen intermediate scavenging

SOD acts as a first line of defense against oxidative stress, converting superoxide anion radicals into hydrogen peroxide. Sen Gupta *et al.* (1993) introduced a chloroplastic Cu/Zn SOD from pea (*Pisum sativum*) into tobacco under control of the CaMV 35S promoter. During chilling stress at moderate light intensity, transgenic plants maintained photosynthetic rates approximately 20% higher than wild-type plants and were able to retain almost 90% of their photosynthetic capacity following chilling stress at high light intensity. Transgenic plants also exhibited reduced levels of light-mediated cellular damage following treatment with the active oxygen generator methyl viologen (Sen Gupta *et al.*, 1993). These results demonstrated that SOD is an important component of the active-oxygen scavenging system in plants; however, a petunia chloroplastic Cu/Zn SOD introduced into tobacco under control of an *rbcs* promoter fragment increased SOD levels, but did not increase tolerance to ozone stress (Pitcher *et al.*, 1991).

Mitochondrial manganese superoxide dismutase (MnSOD) from *N. plumbaginifolia* was introduced into tobacco under control of the CaMV 35S promoter, either as a full-length cDNA or with its mitochondrial leader sequence replaced by a chloroplast transit sequence (Bowler *et al.*, 1991). High-level production of MnSOD in chloroplasts significantly reduced oxidative damage induced by methyl viologen in the light, whereas, under dark conditions, transgenic plants expressing either chloroplast- or mitochondria-targeted MnSOD were significantly more resistant to methyl viologen than control plants. In addition, transgenic plants overexpressing MnSOD in chloroplasts displayed enhanced tolerance to

ozone damage (Van Camp *et al.*, 1994). Chloroplastic iron superoxide dismutase (FeSOD) from *Arabidopsis* coupled to a chloroplast-targeting sequence was introduced into tobacco under control of the CaMV 35S promoter (Van Camp *et al.*, 1996). Expression of FeSOD in transgenic plants was able to protect both the plasmalemma and photosystem II against oxidative damage caused by methyl viologen treatment. This is in contrast to overexpression of MnSOD, which only enhanced protection against ion leakage (Slooten *et al.*, 1995).

Hydrogen peroxide resulting from SOD activity is scavenged by ascorbate peroxidases (APX), glutathione peroxidase (GPX) or catalase. APX and GPX require an ascorbate (AsA) or glutathione (GSH) regenerating cycle, involving the oxidation of AsA to monodehydroascorbate (MDA) or GSH to oxidized glutathione (GSSG). The role of APX in protection against oxidative stress was demonstrated through the production of transgenic tobacco plants expressing antisense copies of the tobacco cytosolic APX gene (Örvar and Ellis, 1997). Transgenic plants exhibited reduced APX activity and significantly higher levels of injury following high-level ozone exposure. Torsethaugen *et al.* (1997), however, observed that transgenic tobacco plants overproducing a chloroplast-targeted cytosolic APX isoform from pea showed no increase in protection against ozone-induced stress, compared to wild-type plants. Badawi *et al.* (2004) transformed tobacco with an *Arabidopsis* APX cDNA fused to a chloroplast transit sequence from *Arabidopsis* glutathione reductase (GR), under control of the CaMV 35S promoter. Transgenic plants showed increased tolerance to the active oxygen-generators methyl viologen and sodium sulfite, as well as enhanced tolerance to salt and water stress, as determined by net photosynthesis. Overexpression of the pepper (*Capsicum annum*) APX-like 1 gene (*CAPOA1*) in tobacco, under control of the CaMV 35S promoter, also resulted in transgenic plants with increase in total peroxidase activity (Sarowar *et al.*, 2005). Transgenic plants exhibited increased tolerance to methylviologen-mediated oxidative stress, in addition to significantly increased growth. These results suggest that the tobacco active oxygen scavenging system can be enhanced by overproduction of APX.

Overexpression of a tobacco glutathione S-transferase with glutathione peroxidase activity (GST/GPX) in transgenic tobacco, under control of the CaMV 35S promoter, enhanced seedling growth under stress conditions (Roxas *et al.*, 1997). Transgenic plants contained higher levels of GSSG and AsA and were able to maintain metabolic activity under stress conditions (Roxas *et al.*, 2000).

Yoshimura *et al.* (2004) introduced a *Chlamydomonas* glutathione peroxidaselike protein, targeted to either the chloroplasts or cytosol, into tobacco under control of the CaMV 35S promoter. Transgenic plants showed increased tolerance to methyl-viologen-induced oxidative stress, chilling stress under high light conditions, and salt stress. Lipid hydroperoxidation was suppressed in leaves of transgenic plants compared to wild-type plants, under stress conditions, leading to maintenance of membrane integrity (Yoshimura *et al.*, 2004).

Protection against methyl-viologen-induced oxidative stress could be increased by overexpressing both SOD and APX in chloroplasts of tobacco plants (Kwon *et al.*, 2002). Chloroplast-targeted Cu/Zn SOD, MnSOD, and APX from pea, all under control of the CaMV 35S promoter, were introduced alone or in combination. Tolerance to oxidative stress was only slightly increased in transgenic plants expressing a single SOD isoform; however, the combination of SOD with APX resulted in greater protection (Kwon *et al.*, 2002).

MDA radicals produced by APX are converted back to AsA through reactions with ferredoxin or MDA reductase. MDA can also spontaneously disproportionate to AsA and DHA, which is reduced to AsA in a reaction catalyzed by DHA reductase (DHAR), using GSH as the electron donor. GSSG is converted back to GSH by GR. Transgenic tobacco plants expressing a chloroplast-targeted human DHAR cDNA, under control of the CaMV 35S promoter, exhibited higher levels of AsA and GSSG than wild-type plants (Kwon *et al.*, 2001). In addition to increased DHAR activity, GR activity was also increased in transgenic T₀ and T₁ plants (Kwon *et al.*, 2001, 2003). Leaf discs of transgenic plants showed a reduction in membrane damage following treatment with methyl viologen or hydrogen peroxide compared to wild-type plants as well as enhanced tolerance

to low temperature and salt stress. Eltayeb *et al.* (2006) introduced cytosolic DHAR from *Arabidopsis* into tobacco, under control of the 35S promoter. Transgenic plants exhibited greater tolerance to ozone, drought, salt, and polyethylene glycol (PEG)-induced stress than wild-type plants, manifested by higher net photosynthesis. A GR gene from *E. coli* was introduced into tobacco under control of the CaMV 35S promoter and targeted to the chloroplast (Aono *et al.*, 1993). Increased GR activity in leaves of transgenic plants was correlated with increased tolerance of photooxidative stress induced by paraquat and sulfur dioxide.

Apoplastic ascorbate oxidase (AAO) catalyzes the oxidation of AsA to MDA using oxygen. A tobacco AAO cDNA was introduced into tobacco plants in both sense and antisense orientation, under control of the CaMV 35S promoter (Yamamoto *et al.*, 2005). In sense orientation, overexpression of AAO led to severe inhibition of germination by high salinity. In contrast, germination frequency, photosynthetic activity, root length, and seed yields were higher in antisense plants at high salinity, than in either wild type or sense plants (Yamamoto *et al.*, 2005). The authors suggest antisense suppression of AAO leads to a relatively low level of hydrogen peroxide accumulation and a high redox state of apoplastic and symplastic ascorbate under salt stress.

Antisense technology in tobacco also provided evidence for an alternative defense mechanism that can compensate for the lack of APX and chloramphenicol acetyltransferase (CAT) (Rizhsky *et al.*, 2002). Double antisense plants were less sensitive to oxidative stress than were transgenic plants lacking either APX or CAT. Increased protection against oxidative stress was correlated with reduced photosynthetic activity, the induction of MDAR, metabolic genes belonging to the pentose phosphate pathway and IMMUTANS, a chloroplast homolog of mitochondrial alternative oxidase (Rizhsky *et al.*, 2002).

2.3.5.2 Lipid peroxidation

Free radical-mediated lipid peroxidation is accompanied by the generation of highly reactive aldehyde degradation products. Aldose/aldehyde

reductases reduce a range of aldehydes and ketones to alcohols, whereas aldehyde dehydrogenases are important enzymes in the conversion of toxic aldehydes to less reactive carboxylic forms. Despite their potential roles in detoxification pathways, functional information on both types of enzyme is currently lacking. Transgenic overexpression in tobacco has provided insights into detoxification of reactive aldehyde species.

A stress-activated alfalfa gene (*MsALR*) encoding a novel plant NADPH-dependent aldose/aldehyde reductase was expressed in transgenic tobacco plants under control of the CaMV 35S promoter (Oberschall *et al.*, 2000). Transgenic plants had greater tolerance to paraquat-induced oxidative stress and reduced accumulation of lipid peroxidation-derived reactive aldehydes. Plants expressing this enzyme were also able to recover from prolonged drought stress and showed tolerance to heavy metal treatment (Oberschall *et al.*, 2000). Rodrigues *et al.* (2006) transformed tobacco with a soybean cDNA (*GmTP55*) encoding an ALDH7 aldehyde dehydrogenase, under control of the CaMV 35S promoter. Transgenic plants accumulated *GmTP55* mRNA in leaves and showed tolerance to salinity (200 mM NaCl) during germination and to water stress during plant growth. Transgenic plants also exhibited enhanced tolerance to H₂O₂- and paraquat-induced oxidative stress, associated with reduced concentrations of lipid peroxidation-derived reactive aldehydes (Rodrigues *et al.*, 2006).

Enzymes of the glyoxalase pathway are required for glutathione-based detoxification of methylglyoxal (MG), a potent cytotoxic compound produced during lipid and carbohydrate metabolism and salt stress. Overexpression of glyoxylase I (*glyI*) from *Brassica juncea*, both under control of the CaMV 35S promoter, conferred tolerance to MG and high salinity in transgenic tobacco (Veena *et al.*, 1999). When these plants were further transformed with the glyoxylase II (*glyII*) gene isolated from rice, transgenic plants exhibited even greater tolerance to high MG and NaCl concentrations and were able to grow, flower, and set seed under continuous salinity stress (Singla-Pareek *et al.*, 2003). Increased levels of glutathione-related antioxidative enzymes enabled plants to resist an increase in MG levels under salinity stress, maintaining a higher GSH:GSSG ratio (Yadav *et al.*, 2005).

2.4 Generalities on Plant Mitochondrial Genomes and Function

Mitochondrial biogenesis and functioning depend on both nuclear and mitochondrial DNA (mtDNA) encoded subunits. The mitochondrial (mt) genome in higher plants is larger and more complex than in other eukaryotes (Schuster and Brennicke, 1994). With some exceptions, plant mitochondrial genomes are maternally inherited, as in most animals. According to cosmid mapping, they may be represented as a single circular map, the so-called master molecule (Palmer and Shields, 1984), which can give rise to subgenomic circles by recombination between inverted or direct repeats (Backert *et al.*, 1997). Subgenomic molecules are often in substoichiometric amounts, and can serve as reservoir for mitochondrial genome evolution (Small *et al.*, 1989). Mitochondrial genomes are quite variable, ranging from 218 to 2500 kb (Palmer and Herbon, 1988). Within one family, the Cucurbitaceae, mitochondrial genome sizes vary between 330 kb and 2,500 kb (Ward *et al.*, 1981). However, the numbers of proteins specified by the smallest and largest of the mitochondrial genomes of the family are roughly similar (Stern and Newton, 1985).

In contrast to animal mitochondria, much of the mtDNA in plants appears to be noncoding. Indeed, all of the known genes account for only 10–20% of mtDNA of various species (Palmer *et al.*, 2000). The noncoding mtDNA includes introns, pseudogenes, nonfunctional chloroplast sequences, and retrotransposons of nuclear origin. The coding part of the *Arabidopsis thaliana* mitochondrial genome consists of about 57 open reading frames (Unsel *et al.*, 1997). Known genes found so far in all the sequenced plant mitochondrial genomes include those for ribosomal RNAs, tRNAs, and several mitochondrial proteins. The mtDNA proteins include several subunits of the complexes of the electron transfer chain: Complex I (NAD 1, 2, 3, 4, 4L, 5, 6, 7 and usually NAD9), Complex III (COB), Complex IV (COX 1, 2, 3), and Complex V (ATP 1, 6, 8, and 9). In addition, the mitochondrial genomes include genes for proteins involved in the biogenesis of cytochrome c (*ccmB*, *FN*, *FC*, and usually *ccmC*), as well as those for several ribosomal proteins.

Plant mtDNA mutants are scarce, as mtDNA usually has a slow rate of nucleotide substitution,

although there are some exceptions (Palmer *et al.*, 2000). Thus, most of the well-studied mitochondrial mutations derive from rearrangements and deletions. In some cases, these rearrangements are neutral and do not confer any marked phenotype, as in the *Nicotiana sylvestris* U mutant (Vitart *et al.*, 1992; Albert *et al.*, 2003). In contrast, several mtDNA reorganizations have been reported to be associated with cytoplasmic male sterility (CMS) that is thought to be caused by the expression of mitochondrial encoded chimeric proteins deleterious to pollen development. Nuclear genes, designated restorers of fertility (*Rf*) impair the production of CMS-associated polypeptides (discussed in Schnable and Wise, 1998; Budar *et al.*, 2002; Wise and Pring, 2002). An important class of *Rf* genes consists of PPR transcription factors that are involved in the control of both chloroplastic and mitochondrial gene expression (Lurin *et al.*, 2004). RNA editing in plant mitochondria, which involves the substitution of some C residues present in the initial transcript for U residues has also been associated with CMS in several species (Schuster and Brennicke, 1994). In contrast to CMS, mtDNA deletion mutants are impaired in both vegetative and reproductive development. They are generally heteroplasmic, with cells harboring a mixture of normal and deleted mtDNA molecules, and are not stably transmitted through sexual reproduction. In maize, mtDNA deletion mutations resulting in abnormal growth are termed nonchromosomal stripe (NCS). A number of maize NCS mutants have been analyzed and shown to result from deletions of portions of essential mitochondrial genes (Newton *et al.*, 1989, 1990; Marienfeld and Newton, 1994). The heteroplasmic plants exhibit distorted growth, attributed to the loss of the mitochondrial protein synthesis in mutant sectors (Hunt and Newton, 1991; Roussel *et al.*, 1991; Newton *et al.*, 1996), but they can shed pollen from normal sectors. The *Arabidopsis* maternally inherited distorted leaf (MDL) phenotype has been associated with rearrangements and deletions in *rps3/rpl16* (Sakamoto *et al.*, 1996). In contrast, an abnormal growth mutant of cucumber, designated MSC (mosaic), is paternally transmitted (Malepszy *et al.*, 1996). Near-homoplasmic deletion mutants stable by sexual reproduction have been reported in *N. sylvestris*, conferring growth retardation and

partial male sterility (Li *et al.*, 1988; Lelandais *et al.*, 1998).

A major function of plant mitochondria is oxidative phosphorylation that couples electron transport through the respiratory chain to proton translocation from the matrix to the intermembrane space, generating an electrochemical gradient necessary for ATP synthase (Siedow and Umbach, 1995). In addition to the main electron transport chain consisting of complexes I–IV, mitochondria in plants and some fungi possess nonproton-pumping respiratory enzymes encoded by the nuclear genome: various external and internal NAD(P)H alternative dehydrogenases bypassing Complex I (Rasmusson *et al.*, 1999, 2004; Moller, 2001) and a cyanide-resistant terminal oxidase (AOX) branching at the level of the ubiquinone pool (Lambers, 1982; reviewed in Vanlerberghe and McIntosh, 1997). In contrast to Complexes I, III, and IV, alternative respiratory enzymes are not directly involved in energy production. Hence, it has been proposed that AOX may prevent over-reduction of the respiratory chain, either in situations of excessive NADH supply as a consequence of a high TCA activity or a high ubiquinone reduction level during inhibition of the COX pathway (Lambers, 1982). Another role for alternative respiratory enzymes may be to minimize the formation of reactive oxygen species (ROS) by over-reduced electron transport chain components (Wagner and Krab, 1995; Purvis, 1997; Moller, 2001), particularly at the ubiquinone pool, and to limit oxidative stress (Popov *et al.*, 1997; Maxwell *et al.*, 1999). Accordingly, several studies have revealed new important functions for plant mitochondria, as the control of cell redox homeostasis and their importance for chloroplastic metabolism (Dutilleul *et al.*, 2003a, b). Plant mitochondria, like animal mitochondria seem to be involved in resistance to biotic and abiotic stresses and cell death control (Purvis and Shewfelt, 1993; Ordog *et al.*, 2002; Tiwari *et al.*, 2002); however, experimental evidence is scarce and precise mechanisms remain to be determined.

In addition to oxidative phosphorylation, mitochondria play numerous roles in plant metabolism (Douce and Neuburger, 1989; Mackenzie and McIntosh, 1999). They are directly involved in the synthesis of nucleic acids, pantothenate, and several amino acids as methionine, glycine, serine, and proline and indirectly, through S-adenosyl

methionine, in all methylation reactions. They also contain branched-chain amino acid transaminases (BCATs) catalyzing the last step of the synthesis and/or the initial step of the degradation of leucine, isoleucine, and valine (Aubert *et al.*, 1996; Anderson *et al.*, 1998; Diebold *et al.*, 2002). Plant mitochondria are involved in the C2 oxidative photosynthetic carbon cycle (Mouillon *et al.*, 1999; Rébeillé *et al.*, 2006) and possess all the necessary enzymatic equipment for *de novo* synthesis of tetrahydrofolate and lipoic acid, serving as cofactors for glycine decarboxylase and serinehydroxymethyltransferase functioning. The final steps of biotin and folate synthesis involve several mitochondrial proteins (Picciocchi *et al.*, 2003). Folates are crucial intermediates for a set of reactions that involve the transfer of single-carbon units (C1 metabolism). Plant mitochondria also contain the enzymatic equipment necessary to transform malonate into the two main building units for fatty acid synthesis, malonyl- and acetyl-acyl carrier protein (ACP), a component of complex I (Gueguen *et al.*, 2000), and have been reported to contribute to leaf lipid synthesis in *Arabidopsis* (Wada *et al.*, 1997).

All the above processes are carried out by nuclear-encoded enzymes and thus manipulation of mitochondrial function might involve transformation of both nuclear and mitochondrial genomes. However, the only photosynthetic organism of which the mitochondrial genomes can be easily manipulated is *Chlamydomonas reinhardtii* (Remacle *et al.*, 2006). Thus, in higher plants transgenesis essentially involves nuclear genes. For example, antisense repression of the mitochondrial NADH-binding subunit of complex I in transgenic potato plants affects male fertility (Heiser *et al.*, 1997). In addition, the introduction of mitochondrial genes in the tobacco nuclear genome has been reported (Hernould *et al.*, 1993; Pineau *et al.*, 2005).

2.4.1 *Nicotiana* mtDNA mutants and transgenics

Tobacco species are a valuable model system for investigating the genetic interaction between mitochondria, chloroplasts, and nucleus of the plant cell. Indeed, the tobacco mtDNA is fully sequenced (Sugiyama *et al.*, 2005), and stable

mtDNA deletion mutants have been obtained by protoplast culture (reviewed in Vedel *et al.*, 1999).

2.4.1.1 *N. sylvestris* mtDNA deletion mutants

In *N. sylvestris*, the female ancestor of the cultivated *N. tabacum*, protoplast culture has given rise to stable mutants with either neutral mtDNA rearrangements (Vitart *et al.*, 1992; Albert *et al.*, 2003) or mtDNA deletions (Li *et al.*, 1988; Chétrit *et al.*, 1992). These deletion mutants, designated CMSI and CMSII due to their partial male sterility, do not exhibit the leaf variegation described above for the other abnormal growth mutants, and their morphological defects are stably transmitted through sexual and somatic generations. This probably reflects the near-homoplasmic mutant composition of their mtDNAs that contain large deletions including the *nad7* sequence encoding the NAD7 Complex I subunit (Pla *et al.*, 1995; Gutierrez *et al.*, 1997; Lelandais *et al.*, 1998). Respiration measurements on mitochondria isolated from CMS leaf tissues showed near complete lack of activity of Complex I and impaired oxidation of glycine, a major respiratory substrate in photosynthetic cells of C3 plants (Douce and Neuburger, 1989). In contrast, the oxidation rate of tricarboxylic cycle substrates and exogenous NADH were increased. Total leaf respiration measured by gas exchange experiments (IRGA) was higher in the mutant than in the WT (Duranceau *et al.*, 2000; Sabar *et al.*, 2000; Dutilleul *et al.*, 2003a). Nonproton-pumping respiratory pathways maintain normal *in vivo* respiration levels in leaves of NAD7-deficient CMS I and II, but these rates are decreased in pollen (Sabar *et al.*, 1998). Survival of these plants depends on the activation of nuclear-encoded internal and external alternative NAD(P)H dehydrogenases, which bypass Complex I (Rasmusson *et al.*, 1999, 2004).

Cyanide-resistant respiration and alternative oxidase (AOX) protein levels were shown to be induced in CMS I and II (Gutierrez *et al.*, 1997; Sabar *et al.*, 2000) as in all the maize NCS plants (Karpova *et al.*, 2002). Because alternative oxidase is nucleus encoded and its induction can be seen at the RNA level, the mutant mitochondria must produce a signal to induce AOX gene

expression. Furthermore, because AOX is also induced by electron transport inhibitors, such as antimycin A (Vanlerberghe and McIntosh, 1997), it is apparent that dysfunction of the mitochondrial respiratory chain results in a strong signal for induction of AOX. However, use of oxygen isotope fractionation to measure the *in vivo* AOX activity (Guy *et al.*, 1989) showed that *in vivo* partitioning through the AOX and the cytochrome (COX) pathways was similar in CMSII and wild-type leaves (Priault *et al.*, 2007). This is not related to marked differences in the redox state of the protein, rather to either expression of a specific AOX gene and/or impaired metabolic control (Vidal *et al.*, 2007). The higher respiration of mature CMSII leaves was supported exclusively by enhanced COX activity (Priault *et al.*, 2007; Vidal *et al.*, 2007). Enhanced activity of the proton-pumping COX route in the mutant can thus be viewed as a compensation for the lack of the first coupling site of the respiratory chain.

Complex I activities are also strongly reduced in a *N. sylvestris* nuclear mutant, termed NMS1, deficient for the NAD4 subunit (De Paepe *et al.*, 1990; Brangeon *et al.*, 2000). Alternative oxidase transcripts and proteins were induced, although to a lesser extent than in CMS, and external NAD(P)H dehydrogenase activities were not increased (Sabar *et al.*, 2000). These results show that lack of NAD4 and NAD7 has different biochemical and physiological consequences. The relationships with the phenotype, that is more affected in NMS1 than in CMS plants, remain however to be determined.

In contrast to respiration, photosynthesis is affected in the *N. sylvestris* CMSI, CMSII, and NMS1 mutants (Sabar *et al.*, 2000). It was demonstrated that mitochondrial Complex I activity is required for optimal photosynthetic performance and is necessary to avoid redox disruption of photosynthesis (Dutilleul *et al.*, 2003a). CMSII plants are also impaired in acclimation to high light (Priault *et al.*, 2006a), but have higher photorespiration (Priault *et al.*, 2006b). These studies show the importance of mitochondria for chloroplast biogenesis and function, previously revealed by physiological and inhibitor studies (reviewed in Krömer, 1995; Raghavendra and Padmasree, 2003).

Moreover, the metabolite profile of CMSII leaves is enriched in amino acids with low C/N,

and depleted in starch and 2-oxoglutarate (2-OG). The accumulation of nitrogen-rich amino acids was not accompanied by increased expression of enzymes involved in nitrogen assimilation (Dutilleul *et al.*, 2005). Analysis of pyridine nucleotides showed that both NAD and NADH were increased by twofold in CMS leaves as compared to wild type, providing strong evidence that pyridine nucleotide availability exerts a crucial influence in the integration of ammonia assimilation and the anaplerotic production of carbon skeletons.

The *N. sylvestris* CMSII mutant was further exploited to explore the role of plant mitochondria in the regulation of cellular redox homeostasis and stress resistance. Acclimation in response to loss of Complex I function is associated with marked spatial and temporal reorganization of antioxidant and defense metabolism that affords enhanced protection to oxidative stress (Dutilleul *et al.*, 2003b). The overall cellular redox state is maintained, as evidenced by lower H₂O₂, and ascorbate and glutathione redox states similar to the wild type. The reorganization of the antioxidant system, both inside and outside the mitochondria, is associated with enhanced resistance to ozone and TMV (Dutilleul *et al.*, 2003b) and with altered reaction to harpin, a bacterial elicitor of the hypersensitive response (Boccaro *et al.*, 2001; Garmier *et al.*, 2002).

To test whether *N. sylvestris* CMS defects directly result from the deletion of *nad7*, CMS transgenic plants carrying an edited *nad7* cDNA fused to the CAMV 35S promoter and to a mitochondrial targeting sequence, were generated (Pineau *et al.*, 2005). The *nad7* sequence was transcribed, translated, and the NAD7 protein directed to mitochondria in CMS transgenics therefore termed CMSII*nad7*, which recovered both wild-type morphology and growth features. Blue-native/SDS gel electrophoreses and enzymatic assays showed that a functional complex was present in CMSII*nad7* mitochondria, demonstrating that lack of complex I in CMSII was indeed the direct consequence of the absence of the NAD7 subunit. Hence, NAD7 is necessary for complex I assembly in plants. The reversion of the AOX expression pattern observed in the transgenic CMS*nad7* was another indication for the restoration of the wild type properties of the respiratory chain. Furthermore, CMS*nad7* plants

harbored amino acid contents similar to the wild type (Dutilleul *et al.*, 2005). Taken together, these results also show that allotopic expression from the nucleus can fully complement the lack of a mitochondria-encoded complex I gene.

2.4.1.2 *N. tabacum* mutants for mtRNA editing

Transgenic tobacco plants transformed with an unedited copy of the mitochondrial *atp9* gene were partially male sterile (Hernould *et al.*, 1993), whereas the expression of the antisense *atp9* RNA abolished the effect of the unedited chimeric gene, by strongly decreasing the abundance of edited *atp9* transcripts (Zabaleta *et al.*, 1996). These results clearly indicate the importance of RNA editing for plant fertility.

2.4.2 Tobacco transgenics of nuclear genes for mitochondrial function and biogenesis

2.4.2.1 Respiratory chain enzymes

To date a few studies of plant transgenics for nuclear genes encoding respiratory proteins have been reported, possibly because most genes encoding main chain subunits are not single copy, and that double mutants are lethal. In *Nicotiana* species, the most extensive studies have concerned the alternative respiratory enzymes, AOX and alternative NAD(P)H dehydrogenases.

Alternative oxidase The AOX protein is a homodimer with the two polypeptides linked by a disulfide bridge (Andersson and Nordlund, 1999; Juszczuk and Rychter, 2003). The reduced form is more active than the covalently linked oxidized form in *in vitro* assays (Umbach and Siedow, 1993; Day *et al.*, 1994) and the enzyme is further activated by pyruvate and other α -ketoacids (Millar *et al.*, 1993). However, the AOX activation state *in vivo* is not well understood (Millenaar *et al.*, 2002). AOX genes belong to a multigene family, comprising at least two subfamilies, termed AOX1 and AOX2, with only limited nucleotide homology (Considine *et al.*, 2002)

Sense and antisense DNA constructs of the *N. tabacum* *Aox1* gene were introduced into tobacco, and transgenic plants with both increased and decreased levels of the AOX protein were analyzed (Vanlerberghe *et al.*, 1994, 1995). Antisense cultured cells could not survive in the presence of inhibitors of the cytochrome pathway (Vanlerberghe *et al.*, 1997, 2002), confirming that a critical function of AOX may be to support respiration when the main pathway is impaired.

Tobacco AOX sense and antisense transgenics were further used to demonstrate the critical role of plant mitochondria in response against abiotic and biotic stresses, including cell death (Maxwell *et al.*, 1999; Ordog *et al.*, 2002; Robson and Vanlerberghe, 2002; Gilliland *et al.*, 2003; Amirsadeghi *et al.*, 2006). In particular, antisense AOX transgenics were reported to be more susceptible to cell death inducers. However, subsequent measurement of AOX activity by oxygen isotope discrimination indicated that the *in vivo* AOX activity measured by oxygen isotope discrimination was similar in transgenics with either low or high protein amounts as in the wild type (Guy and Vanlerberghe, 2005), showing that complex regulations of whole mitochondrial metabolism rather than AOX activity *per se* was involved in the previously observed stress responses.

NAD(P)H dehydrogenases Overexpression of the potato *NDB1* gene in transgenic *N. sylvestris* demonstrated that this gene encodes an external dehydrogenase specific for NADPH and dependent on calcium for activity. Transformed plants had increased protein levels for alternative oxidase and uncoupling protein, indicating crosstalk for the different categories of energy-dissipating proteins that bypass oxidative phosphorylation (Michalecka *et al.*, 2004)

2.4.2.2 TCA cycle enzymes

Isocitrate dehydrogenase Transgenic *N. tabacum* plants overexpressing NADP⁺-dependent mitochondrial isocitrate dehydrogenase (mtICDH) displayed a measurable increase in the reductive activation of AOX in comparison with wild type, implicating this enzyme in the redox activation

of AOX (Gray *et al.*, 2004). These results support the hypothesis that mtICDH may be a regulatory switch involved in tricarboxylic acid cycle flux and the reductive modulation of AOX.

Aconitase In animals, aconitase is a bifunctional protein that is involved in both TCA cycle functioning and RNA processing. A similar role was recently demonstrated in *Arabidopsis* and *N. benthamiana* transgenics. Aconitase-silenced plants displayed a delayed hypersensitive response (HR), suggesting that aconitase might play a role in mediating oxidative stress and regulating cell death (Moeder *et al.*, 2007).

2.4.3 Other mitochondrial functions in relation with stress tolerance

Transgenic tobacco cells accumulating free proline by silencing proline dehydrogenase expression were tolerant to osmotic stress (Tateishi *et al.*, 2005). Transgenic tobacco plants overexpressing the tomato mitochondrial small heat-shock protein exhibited normal morphology and growth rates, but showed higher tolerance to heat stress, whereas antisense plants were more susceptible (Sanmiya *et al.*, 2004).

2.4.4 Concluding remarks

Nicotiana mtDNA mutants and nuclear transgenics for mitochondrial enzymes have been invaluable tools for the study of plant respiration and of the involvement of mitochondrial metabolism in cell redox homeostasis, stress resistance, and cell death, in plants as in animals (Desagher and Martinou, 2000). However, in photosynthetic cells, the crosstalk between mitochondrial and chloroplast metabolism seems to be of crucial importance and needs further investigation.

2.5 Plastid Transformation

N. tabacum was the first higher plant to receive an engineered plastome (Svab *et al.*, 1990) and

all basic principles of plastid transformation technology are derived from the work in this species. Tobacco was chosen mainly due to its performance in tissue culture and to the fact that the tobacco plastome was the first to be fully sequenced (Shinozaki *et al.*, 1986; last update Yukawa *et al.*, 2005)

A query to PubMed for plastid or chloroplast transformation results in more than 25 review articles. Some of these are compiled in Table 1. This chapter does not attempt to give a fully comprehensive overview on all data published on tobacco plastid transformation. Rather, it presents aspects that complement the aforementioned reviews, such as significant findings or those, which have not been fully discussed previously. Almost all of the review articles stress the potential advantages of plastid versus nuclear transformants, i.e., high expression level, engineering and co-expression of several genes in polycistronic operons, transgene containment due to maternal inheritance, lack of gene silencing, and unknown position effects and precision of engineering via homologous recombination. The emphasis on potential benefits combined with limited discussion of problems or failures has generated very high expectations with respect to the value of the technology as a platform for recombinant protein expression or generation of agronomically important traits. It should be kept in mind, however, that expectations are not always met. Expression levels of recombinant proteins may indeed be extremely low if the protein of interest is efficiently degraded in the organelle (Leelavathi and Reddy, 2003; Birch-Machin *et al.*, 2004). Also, the lack of post-translational modifications such as glycosylation in plastids severely limits the value of this expression platform where higher order modification of the end product (e.g., a human protein) is of importance for function and/or regulatory aspects.

2.5.1 Vector design

Plastome transformation is either based on the activity of the organelle's own endogenous recombination capacity or the use of a heterogeneous recombination system, such as the phiC31 phage integrase.

2.5.1.1 Use of the endogenous recombination system

Plant plastid transformation has mainly been achieved through the use of sequences on an engineered transformation vector containing sufficient homology to the target plastome to allow for homologous recombination mediated by the organelle's recombination system. These so-called "homologous flanks" are generally approximately 1 kbp in size assuming that shorter flanks would reduce recombination efficiency while significantly longer flanks make cloning more difficult. Expression cassettes in plastid transformation vectors must take into account that regulatory elements, such as promoters, 5' untranslated regions (UTRs), ribosome binding sites, and 3' UTRs need to be compatible with the plastid gene expression machinery. A heterologous RNA polymerase can also be used for transcription, if the expression cassette is equipped with a suitable promoter (McBride *et al.*, 1995). Further modifications may include a "downstream box" for enhanced translation efficiency (Kuroda and Maliga, 2001; Herz *et al.*, 2005), fusion, and/or purification tags for enhanced protein stability and facilitation of protein extraction (Leelavathi and Reddy, 2003), and proteolysis recognition sites

if authentic starting amino acids are required for a processed protein end product (Staub *et al.*, 2000). A sample plastid transformation vector for the insertion of a dicistronic operon is depicted in Figure 2. A selectable marker gene is certainly also required for the transformation process. If the second cistron is used for this purpose, it is safe to assume that the protein encoded by the first cistron is expressed in the recovered transformants. Alternatively, a selection marker cassette could also be positioned elsewhere on the same transformation vector or on a different transformation vector and used in a co-transformation approach, which works efficiently in plastid transformation (Carrer and Maliga, 1995; Herz *et al.*, 2005). Up to four genes combined in a single operon were successfully introduced into the tobacco plastome (Lossel *et al.*, 2003; Quesada-Vargas *et al.*, 2005), and a principle limitation of the number of cistrons that can be co-introduced into and co-expressed in a plastome cannot be seen.

Note that not all elements depicted in Figure 2 are indispensable. Thus, separate promoters are not required, if transcription is mediated by endogenous transcription start signals (Staub and Maliga, 1995). Such "operon extension vectors" are described in detail by Herz *et al.*

Figure 2 Elements of a dicistronic tobacco plastid transformation vector

(2005). It is also possible to use incomplete expression cassettes on co-transforming, separate transformation vectors, since complete and functional expression cassettes can be assembled by homologous recombination inside the plant after transformation treatment (Herz *et al.*, 2005).

2.5.1.2 Use of the *phiC31* phage integrase

It has been speculated that difficulties in transferring the plastid transformation methods developed for tobacco to other species might be related to differences in the efficiencies of the endogenous recombination systems among different species. It is therefore useful to investigate the suitability of heterogeneous systems. Lutz *et al.* (2004) demonstrated that the integrase of phage *phiC31* can be used for integrating foreign DNA into the tobacco plastome if supplied via expression from a nuclear gene and targeted to the plastid or—although less efficiently—if supplied through a transiently expressed plastid vector. While the approach is certainly interesting, its value remains to be demonstrated. Integration using this recombination system requires the presence of a suitable recognition sequence (*attB*) at the desired integration locus of the target plastome. This, however, must be generated through the endogenous recombination system first, which may be difficult, if indeed the efficiency of the endogenous recombination system was the limiting factor in a particular species.

2.5.2 Target tissues

The larger size of chloroplasts in comparison with proplastids made leaf explants the target tissue of choice for plastid transformation treatments. Indeed, green tissue or protoplasts prepared thereof were the targets for the first successful plastid transformations in tobacco (Svab *et al.*, 1990; Golds *et al.*, 1993) and other species (*N. plumbaginifolia*: O'Neill *et al.*, 1993; *Arabidopsis thaliana*: Sikdar *et al.*, 1998; *S. tuberosum*: Sidorov *et al.*, 1999; *L. esculentum*: Ruf *et al.*, 2001; *B. napus*: Hou *et al.*, 2003; *Lesquerella fendleri*: Skarjinskaia *et al.*, 2003; *Petunia hybrida*: Zubko *et al.*, 2004; *Lactuca sativa*: Lelivelt *et al.*, 2005; *Populus alba*: Okumura *et al.*, 2006). However, nongreen tissues, such as in tobacco, protoplast-derived microcolonies (Huang *et al.*, 2002), albino leaves (Klaus *et al.*, 2003) or cell suspensions (Langbecker *et al.*, 2004), and cell cultures of other species (*Oryza sativa*: Khan and Maliga, 1999; *Daucus carota*, *G. hirsutum*: Kumar *et al.*, 2004a, b; *Glycine max*: Dufourmantel *et al.*, 2004) have also been used successfully. It is therefore evident that plastid transformation does not require fully developed chloroplasts. This is of significance since in important crops, such as the cereals, regeneration from green tissues is not yet possible.

2.5.3 Methods of gene delivery

There are two methods to deliver transforming DNA into tobacco plastids, which make it possible

to recover stably transformed lines, the particle gun-mediated biolistic process and treatment of isolated protoplasts with PEG in the presence of suitable transformation vectors. For detailed protocols the reader is referred to the reviews listed in Table 1 (see e.g., Dhingra and Daniell, 2006 and Lutz *et al.*, 2006a, for particle bombardment and Kofer *et al.*, 1998a for PEG treatment). The mechanism of entry of the transforming DNA is assumed to be by mechanical impact in the case of the biolistic procedure: microprojectiles supposedly penetrate the organelle's envelope thus carrying the DNA inside. It is not known whether or how a chloroplast envelope would reseal after penetration. With PEG-treatment the mechanism of DNA entry into a cell and then through the two envelope membranes is even less clear. The assumption derived from transient expression assays with nuclear reporter constructs is that PEG produces transient discontinuities or "holes", in the plasma membrane through which DNA can enter into the cell (Paszkowski *et al.*, 1984). Such a process would lead to entry of plasmids into the cytosol, and it remains completely unknown how, subsequently, the DNA could reach the inside of an organelle. If, however, there is transfer of DNA from the cytosol into organelles that have an envelope consisting of two membranes, then it is also conceivable that, through particle bombardment plasmids are primarily delivered into the cytosol and enter the organelle afterward. Experiments that would elucidate the mechanisms of DNA uptake are difficult to conceive. In tobacco, plastid transformation is highly efficient irrespective of the method used for DNA delivery and the precise pathway of DNA entry.

It is important to note that a femtosyringe-based microinjection procedure was used to deliver reporter genes into plastids (Knoblauch *et al.*, 1999; Van Bel *et al.*, 2001), and transient reporter gene expression was clearly achieved; however, stable transformants were not generated. When species, closely related to tobacco, prove recalcitrant to plastid transformation, an interesting approach can be used exploiting the fact that plastids in tobacco can be transformed. Kuchuk *et al.* (2006) transformed the plastomes of five different recalcitrant solanaceous species after generating cytoplasmic hybrids with tobacco supplying the nuclear genome and the other species donating the cytoplasmic genomes.

2.5.4 Selection systems

Selection systems for higher plant plastid transformation need to fulfil several highly demanding requirements. Selective advantage must be generated on two levels, that of the single plastid and that of the individual cell. It is assumed that the initial transformation event involves a single or few of the high number—up to 10 000 per cell in a fully developed leaf (Bendich, 1987)—of plastid chromosomes only. The kinetics of the increase of the transplastome copy number during selection is not known. It has been speculated that the presence of an origin of replication on the transformation vector might allow for multiplication of the vector inside the organelle, which increases the number of transformation events (Dhingra and Daniell, 2006). However, there is no experimental evidence supporting this assumption. Moreover, the origin of replication used by the Daniell laboratory was shown to be dispensable for replication (Muhlbauer *et al.*, 2002). While prolonged presence of vector plasmid molecules has indeed been observed, it is more likely that such molecules are derived from recombination rather than replication events (Staub and Maliga, 1994; Klaus *et al.*, 2004). Replication of the plastome itself, possibly in combination with gene conversion events (Khakhlova and Bock, 2006), therefore, appears to be the cause of increase of transplastome copy number in an organelle. Although molecules are exchanged between individual plastids of a cell (Kohler *et al.*, 1997), there is no evidence that this process also involves plastid DNA. Therefore, the assumption is that plastid DNA replication and plastid division are both necessary processes leading to the increase of numbers of organelles containing transformed DNA copies inside a cell. Selection systems need to favor those plastids that contain the highest proportion of transformed plastomes and/or those cells that contain the highest proportion of plastids with transformed plastomes. At the same time, nontransformed plastids and cells without transformed plastids need to stay viable. Selection pressure, therefore, has to be adjusted carefully.

It is noteworthy that transmittance of different plastome copies to the products of organelle division and transmittance of organelles to the products of cell division are both random processes. Segregation, i.e., the generation of cells,

which are homozygous with respect to their plastomes, termed “homoplastomic”, from cells containing different types of plastomes, termed “heteroplastomic”, does not require selective pressure. Segregation is a statistical process (Michaelis, 1966) and cannot be avoided, unless there is counter selection, for example, in the case of the disruption or deletion of an essential gene (Drescher *et al.*, 2000).

Different schemes of selection were used in tobacco plastid transformation. Selection using an antibiotic always comprised the initial step of primary selection, and in some schemes this was followed by secondary selection using a different inhibitor or a pigmentation phenotype. Screenable markers, such as the GFP were also used to assist detection of transformed sectors of tissues in tobacco (Khan and Maliga, 1999) and other species (Sidorov *et al.*, 1999; Skarjinskaia *et al.*, 2003).

2.5.4.1 Primary selection using antibiotic inhibitors

Different selection markers have been used successfully, all of which are based on tolerance toward aminoglycoside antibiotics. Tolerance is either based on mutations of the ribosomal RNA target site (Svab *et al.*, 1990) or on the expression of detoxifying enzymes (Carrer *et al.*, 1993; Svab and Maliga, 1993; Huang *et al.*, 2002). Aminoglycoside antibiotics are inhibitors of protein biosynthesis on prokaryotic/organelle ribosomes and should, therefore, also inhibit mitochondrial protein biosynthesis. Detoxifying enzymes should reduce the concentration of the antibiotic in question in the whole cell and should, therefore, also reduce the effect of the inhibitors on mitochondria. However, in the case of insensitive plastid ribosomal RNA target sites it is unclear why the supposed inhibition of protein biosynthesis in the mitochondria is tolerated by

the cell. Possibly, growth and development *in vitro*, i.e., under heterotrophic conditions, can occur with reduced mitochondrial protein biosynthesis.

Aminoglycoside antibiotics that have been used successfully for the selection of plastid transformants in tobacco are listed in Table 2.

A report that was published under the interesting title “Marker free transgenic plants:” received considerable attention. The plant nuclear gene *badh* encoding BADH, in combination with betaine aldehyde as the selective agent, was described as an alternative selection system and was claimed to be far superior to those listed in Table 2 (Daniell *et al.*, 2001). Certainly, irrespective of its functionality as a selection marker, the *badh* gene can be expressed in higher plant plastids (Kumar *et al.*, 2004a, b). However, the conclusion presented in Daniell *et al.* (2001) is curious in that the vectors used for transformation maintained other selectable markers in addition to a *badh* selection cassette (compare Maliga, 2005). Furthermore, neither the Daniell group nor any other laboratory has since reported successful selection using betaine aldehyde, and a number of laboratories failed to independently reproduce the results. In the absence of reproducibility, attempts to select plastid transformants via the betaine aldehyde system should be avoided. Chloroplast engineering requires a substantial investment of human and laboratory capital and other methods of selection have proven to be effective.

Alternatives to the antibiotic resistance genes listed in Table 2 have not proven reproducibly effective. Herbicides could not be used for selection, although expression of herbicide resistance genes is possible in plastids and can lead to considerable levels of tolerance (Daniell *et al.*, 1998; Iamtham and Day, 2000; Lutz *et al.*, 2001; Ye *et al.*, 2001, 2003). A similar situation was found for other marker genes, which have been successful in selection of nuclear transformants, such as hygromycin phosphotransferase (Dhingra

Table 2 Selective agents and selection marker genes in tobacco plastid transformation

and Maliga, personal communication), sulfadiazin insensitive dihydropteroate synthase, and blasticidin deaminase (U.-H. Koop Lab, personal communication).

2.5.4.2 Secondary selection

Herbicide tolerance can be used to accelerate segregation once a sufficient number of transformed plastid genome copies have accumulated (Iamtham and Day, 2000). As an alternative, pigmentation can help detect sectors containing transformed plastome copies and at the same time considerably accelerate segregation toward homoplasmy. Klaus *et al.* (2003) used targeted inactivation of pigmentation-related plastid genes to generate lines with pale to white phenotypes. In a second round of transformation, the inactivated genes were reintroduced. Transformation events re-established the wild-type green phenotype, which made it possible to easily detect such transformed regenerants. Regreening could not be achieved by spontaneous mutations. Thus, the appearance of green regenerants clearly indicated true plastid transformation events. In addition, PCR analysis showed that the first regenerated shoots were already homoplastomic for the second transformation, therefore the usual repetitive cycles of regeneration in the presence of selection was no longer required. Evidently, under the culture conditions chosen, the green tissues had a strong selective advantage over the pigment deficient ones.

2.5.5 Strategies for removal of selectable marker

Public concern, whether scientifically justified or not, requests removal of antibiotic resistance marker genes from transgenic plants intended for human consumption or animal feed. Marker removal approaches are of benefit when the number of available selection markers is low and multiple consecutive transformation steps are required for generating a desired end product. Furthermore, expression of marker genes, not required in established transplastomic lines, constitutes an unnecessary metabolic burden on transplastomic plants. In plastid transformation, four different strategies are available and have been successfully

applied to tobacco: use of direct repeats included in the transformation vector, use of separate transformation vectors harboring selection marker and gene of interest in a co-transformation approach, use of site-specific recombinases with segregation of different plastomes, and use of a transformation vector architecture, which leads to co-integrate formation and subsequently to automatic marker elimination.

2.5.5.1 Direct repeats for marker removal

Higher plant plastids have a highly active recombination system. This needs to be considered, when designing transformation vectors to avoid undesired rearrangement through direct repeat-mediated loop-out recombination of introduced sequences (Maliga *et al.*, 1993; Zou *et al.*, 2003). On the other hand, direct repeat-mediated loop-out recombination can also be used for marker removal (Iamtham and Day, 2000). Since the timing of loop-out recombination cannot be controlled, and since transformants cannot be distinguished from wild-type lines, this system requires a secondary selection system, e.g., herbicide resistance (Iamtham and Day, 2000). Interestingly, the same approach can be applied for targeted gene inactivation in chloroplasts (Kode *et al.*, 2005, 2006).

2.5.5.2 Co-transformation and segregation

Ye *et al.* (2003) used two different vectors and a selection scheme, initially based on spectinomycin as the selective inhibitor and subsequently on herbicide selection. The rationale behind this scheme is that initial selection with herbicides is not possible in plastid transformation. However, after enrichment for transplastomic plastome copies, the level of herbicide tolerance might be sufficient to, in a heteroplastomic situation, allow for segregation of lines, which carry the herbicide but not the antibiotic resistance genes. Indeed, 20% of the recovered lines fulfilled this criterion. As with direct repeat-mediated loop-out recombination, the approach requires a secondary marker, i.e., the resulting lines are not “marker-free”, and the expression of the secondary marker might constitute an unnecessary metabolic burden.

2.5.5.3 Use of site-specific recombinases

Hajdukiewicz *et al.* (2001) and Corneille *et al.* (2001) independently and simultaneously introduced CRE recombinase-mediated marker removal from transplastomic tobacco. The expression of the CRE protein-encoding gene, derived from the P1 bacteriophage, leads to insertion or excision of sequence elements, provided that recognition elements, *loxP* sites, are present on the recombination substrate molecules. Marker gene removal thus requires directly repeated *loxP* elements flanking the marker gene in the plastome. CRE recombinase can be expressed from a nuclear expression cassette, translated in the cytosol and then introduced into the plastid through the organelle's import machinery. Surprisingly, not only the desired excision events are observed, but additional plastome rearrangements that are not necessarily only due to “cryptic” *lox* sites in the plastome (Corneille *et al.*, 2003) but are either based on short direct repeats or on recombination “hot spots”. CRE recombinase seems to generally increase recombination activity in the plastome. It is not understood why the frequency of plastome rearrangements depends on the way, in which the recombinase is introduced into the transplastomic lines. This can either be by *Agrobacterium*-mediated stable or transient (Lutz *et al.*, 2006a, b) nuclear transformation or by crossing a transplastomic line with a suitable nuclear transformant. Marker removal through *Agroinfiltration*-based transient expression (Lutz *et al.*, 2006a, b) is efficient and clearly is preferable since removal of stably integrated expression cassettes from the nuclear genome is not necessary. In addition, plastome rearrangements are not occurring once CRE recombinase is no longer present.

2.5.5.4 Automatic marker removal through co-integrate formation

Integration of foreign DNA into the plastome mediated by two homologous flanking regions requires two events of reciprocal recombination. If these recombination events occur more or less simultaneously, the resulting transformed plastome contains the sequences flanked by the homologous regions. Klaus *et al.* (2004) observed that occurrence of the recombination events at

different time points is the rule rather than the exception, and that both homologous flanks participate in the initial recombination event with the same probability. Recombination via—initially—a single flank only leads to the formation of a co-integrate, i.e., the whole vector plasmid will be integrated and the homologous flanks will be duplicated to generate direct repeats. This is shown for integration via the 5' homologous flank in Figure 3a. Note that the process occurs with the same frequency via the 3' flank. Because of the presence of direct repeats, which present substrates for loop-out recombination, co-integrates are inherently unstable and either reversal to wild-type plastomes (recombination between elements “2” in Figure 3a) or generation of molecules identical

Figure 3 Marker-removal via co-integrate formation. (a) conventional transformation vector and co-integrate resulting from recombination via the 5' flank; (b) novel transformation vector with the selection marker cassette outside the homologous flanks

to those formed through two simultaneous recombination events (recombination between elements “5” in Figure 3a) will occur.

Klaus *et al.* (2004) took advantage of the fact that the vector backbone is initially integrated and is removed by the organelle’s recombination system later by positioning the selection marker expression cassette outside the sequences between the homologous flanks (Figure 3a). As long as the presence of a selection inhibitor is maintained there will be a selection against wild-type plastomes and the number of plastomes containing co-integrates will increase. On removal of the selection pressure co-integrates are resolved resulting in plastomes identical to those of the acceptor lines and marker-free plastomes containing the gene of interest. Phenotypical selection using pigmentation or other visible markers assists in detecting the regenerates containing the gene of interest. However, it has also been shown that PCR screening easily identifies the transformed regenerants. Thus, the approach does not depend on the availability of pigment mutant lines. A simple change in vector design leads to automatic marker removal without the need for any other genes or markers.

2.5.6 Chloroplast biology and engineering of important traits

After the first successful demonstration of stable plastid transformation in tobacco (Svab *et al.*, 1990), the methodology has been utilized for understanding basic chloroplast biology and expressing desirable traits. It is noteworthy to mention that advances in the understanding of chloroplast gene expression using plastid transformation in tobacco have led to more efficient vector designs and thus better expression of introduced genes.

2.5.6.1 Understanding chloroplast biology

Chloroplast gene expression is regulated at transcriptional, translational, and post-translational levels. All these stages of gene expression regulation have been investigated in transplastomic tobacco. Understanding of chloroplast gene function and its relation to chloroplast

biology was achieved via targeted inactivation of individual genes. Availability of the tobacco chloroplast genome sequence was very beneficial in this exercise, as the sequence and identity of individual genes were already known (Shinozaki *et al.*, 1986; Yukawa *et al.*, 2005). Only the crucial plastid transformation experiments that contributed toward advancing our understanding of chloroplast biology are discussed here.

The chloroplast genetic machinery is prokaryotic in nature and very strong biochemical evidence existed for a functional plastid genome-derived RNA polymerase activity (Hu and Bogorad, 1990; Hu *et al.*, 1991). This fact was not only confirmed via plastid transformation but individual function of the RNA polymerase subunit genes was also ascertained using the transplastomic lines where the subunit genes had been knocked out (Allison *et al.*, 1996; Hajdukiewicz *et al.*, 1997; Serino and Maliga, 1998; De Santis-Maciossek *et al.*, 1999; Krause *et al.*, 2000). Further, the basal plastid promoter and its constituents were identified using a series of promoter deletions in transplastomic tobacco (Allison and Maliga, 1995; Shiina *et al.*, 1998).

The chloroplast genome contains light-regulated photosynthesis-related genes and their expression generally responds positively to light and anterograde signals. Specifically, red and blue light are involved in upregulation of gene expression (Sexton *et al.*, 1990; Grover *et al.*, 1999). The blue light-regulated promoter region of the *psbD*-C operon was initially investigated in barley and *in vitro* experiments clearly defined the elements responsible for blue light perception (Christopher *et al.*, 1992). Function of the blue light-regulated *psbD*-C promoter was confirmed and specific elements characterized using plastid transformation (Allison and Maliga, 1995). It has recently been reported that green light, thought to be a benign part of the light spectrum, negatively regulates plastid gene expression (Dhingra *et al.*, 2006). It would be interesting to identify DNA elements that participate in this unique phenomenon using plastid transformation.

Perhaps one of the most important discoveries that resulted from plastid transformation experiments in tobacco was the identification of second transcription machinery in the plastids (Allison *et al.*, 1996; Hajdukiewicz *et al.*, 1997; Kapoor *et al.*, 1997). The beta subunit of plastid-encoded

RNA polymerase was disrupted and that resulted in the detection of the additional polymerase activity (Allison *et al.*, 1996). The information regarding two polymerase plastid transcription machineries is now being incorporated into plastid transformation vector designs.

The chloroplast genome sequence of tobacco revealed the presence of *ndh* genes based on homology with mitochondrial respiratory chain complex I subunit genes coding for proton pumping NADH:ubiquinone oxidoreductase (Shinozaki *et al.*, 1986; Fearnley and Walker, 1992), but the existence of a functional respiratory chain complex I in chloroplasts was a matter of debate. Individual *ndh* subunits were disrupted in tobacco and existence of a functional *Ndh* complex in mature chloroplasts was still demonstrated. It was also shown that the complex is dispensable under normal growth conditions but may be essential under stress (Burrows *et al.*, 1998; Kofer *et al.*, 1998b).

Other targeted inactivation studies include *rbcL* knockout to facilitate Rubisco engineering (see Section 2.6; Kanevski and Maliga, 1994). The *sprA* gene was proposed to participate in maturation of 16S rRNA but transplastomic plants with an inactivated *sprA* were normal (Sugita *et al.*, 1997). In another study attempts were made to disrupt the *ycf9* gene but were unsuccessful. Although actual function of *ycf9* was not ascertained, it was clear that it had a vital role in plant survival (Maenpaa *et al.*, 2000). Another open reading frame coded by *ycf5* was targeted for deletion to study its function. Null mutants of *ycf5* were pale green and electron flow around photosystem II (PS II) was found to be affected indicating a role of this gene product in the generation of functional PS II units (Tsuruya *et al.*, 2006). It was revealed that the *rps18* gene is indispensable in higher plants, whereas this gene is absent in plastids of nongreen unicellular organisms (Rogalski *et al.*, 2006). Targeted inactivation of *psaJ* gene had no apparent effect on plant growth but under limiting light conditions it is essential for efficient photosystem I excitation (Schottler *et al.*, 2007). There are other open reading frames (ORFs) in the chloroplast genome of higher plants whose function remains to be understood. Chloroplast transformation approach will continue to expand our understanding of chloroplast biology.

2.5.6.2 Recombinant proteins

Several recombinant proteins have been expressed via plastid transformation in tobacco. Some of the recent reviews provide a list of these proteins with other pertinent details (Daniell *et al.*, 2005c; Grevich and Daniell, 2005). In order to avoid redundancy only recent reports are mentioned here. Four new reports add to the expanding list of biopharmaceutical proteins being expressed via tobacco plastid transformation. Foot-and-mouth disease virus (FMDV) *VP1* gene was expressed at 2–3% of total soluble protein in tobacco chloroplasts (Li *et al.*, 2006a). Li *et al.* (2006b) also expressed a partial spike (S) protein of SARS-CoV to generate a vaccine against the severe acute respiratory syndrome (SARS) corona virus in tobacco. Authors indicate this as a first step toward creating an oral vaccine against the SARS virus. Another report details successful expression of anti-Epstein-Barr Virus viral capsid antigen (VCA) using tobacco plastid transformation at 0.04% tsp (Lee *et al.*, 2006). For all these reports immunogenicity remains to be tested. More recently vaccine against amoebiasis has been generated in transplastomic tobacco. The *LecA* gene used for generating the antigen is expressed at 6.3% tsp and is able to elicit an immunogenic response in mice (Chebolu and Daniell, 2007). These reports present exciting evidence that transplastomic engineering may produce important products for human benefit. However, successful implementation of such technologies will depend on plant cultivation at an agricultural scale. Another recurring theme is the mention of “oral vaccines”, yet these proteins are being expressed in a nonfood and nonfeed crop, tobacco. If oral vaccines are to become a reality, the protein will need to be extracted from tobacco and then administered orally or expressed in other edible crops like tomato.

Other important recombinant proteins can be grouped under the biomaterials, enzymes, and amino acids categories. Two biopolymers have been successfully expressed in transplastomic tobacco. These include p-hydroxybenzoic acid and polyhydroxybutyrate (Lossel *et al.*, 2003; Viitanen *et al.*, 2004). If the production can be increased to industrial levels, plant-based generation of biopolymers will be extremely beneficial in the health care sector. Xylanase (an enzyme) and

tryptophan (an amino acid) have also been reported to be well expressed when biosynthesis genes were integrated into the tobacco plastid genome (Zhang *et al.*, 2001; Leelavathi *et al.*, 2003).

2.5.6.3 Agronomic traits

The tobacco plastid genome has been engineered for conferring biotic and abiotic stress tolerance. Disease and insect resistance have been engineered by expressing antimicrobial peptide and the Cry family of genes (see De Cosa *et al.*, 2001; Daniell *et al.*, 2005c; Grevich and Daniell, 2005; Chakrabarti *et al.*, 2006). Drought tolerance was conferred in tobacco by the expression of trehalose phosphate synthase gene (Lee *et al.*, 2003). Effective phytoremediation of mercury was also reported in transplastomic tobacco expressing the bacterial *merA* and *merB* genes (Ruiz *et al.*, 2003).

2.5.6.4 Inducible expression

There are several reasons, why inducible expression in plastids is desirable. Metabolic drain during growth and development could be avoided, if an economically feasible preharvest induction was available. Likewise, negative effects of gene product(s) or metabolic changes caused by the function of introduced genes might be a problem, if expression was constitutive. Furthermore, presence of pharmaceutical gene products or metabolites throughout the whole growth phase of a plant is more demanding in terms of biosafety and regulatory control than precisely controlled short-term presence. Finally, for basic research it would be valuable if plastid gene expression could be switched on and off at desired time points.

Expression of plastid genes is mediated by regulated promoters, which supply transcriptional control depending on physiological, developmental, or tissue specificity parameters. Therefore, inducible expression in plastids can only be achieved using heterologous control elements.

The first system that was described used a plastid transgene under the control of the phage T7 promoter in combination with import of the T7 polymerase encoded by a nuclear transgene (McBride *et al.*, 1995). Although using this system-

controlled expression is achieved to a certain extent (Magee *et al.*, 2004) and negative effects on fertility observed during constitutive expression of PHB genes were abolished, when these genes were transcribed by an ethanol induced T7 polymerase (Lossel *et al.*, 2005), the system is not optimal. Plastid gene expression is altered in the presence of T7 polymerase even if they do not contain a T7 promoter (Magee and Kavanagh, 2002), and the low level of expression typical for most nuclear inducible systems even in the noninduced state may be sufficient to cause an undesirable phenotype (Magee *et al.*, 2004).

An alternative approach uses constitutive repression of a transgene by the lac repressor and induction by application of isopropyl- β -D-galactopyranoside (IPTG), which leads to an increase of the protein in question by about 20-fold (Mühlbauer and Koop, 2005). While this system is attractive since it uses regulatory elements located in the plastid only and does not require additional nuclear transgenes, it is also not optimal, since, probably due to read-through transcription from a different promoter, there is low level expression in the noninduced state and spraying IPTG in greenhouses or even on open fields does not seem economically feasible. This problem might be at least partially overcome by performing postharvest induction (Mühlbauer and Koop, 2005).

Buhot *et al.* (2006) reported using the *E. coli* *groE* heat shock promoter, a eubacterial promoter, which is not recognized by the nuclear (NEP)- and plastid (PEP)-encoded transcription systems present in plastids. Controlled expression is achieved through a chimeric transcription factor that mediates interaction of NEP and the eubacterial promoter. The system was tested and shown to function via transient expression of the transcription factor, and the performance in stably transformed plants remains to be seen. Like in the case of T7 polymerase/T7 promoter, induction is indirect, i.e., via a protein that is encoded by a nuclear transgene.

Recently, a further approach was described by Tungsuchat *et al.* (2006). It is based on CRE recombinase-mediated rearrangement of a transplastome. In this case, a gene of interest lacking an AUG translation start codon is linked to the nonexcised start codon of the marker gene through excision of the selection marker gene. The

advantage of the system lies in the fact that it is not sensitive to read-through transcription. Control is by generating a translatable open reading frame. Prior to excision there is no detectable gene product (GFP) of the gene of interest, while accumulation of GFP is found up to be 0.3% of the total cellular protein after excision. Again, a transgene expressed from the nucleus is required to trigger plastid expression: primary transplastomic lines harboring an inactive gene of interest were transformed in their nuclear genome using *Agrobacterium*-mediated gene transfer. It remains to be seen, how the approach can be adapted for practical purposes.

While all the approaches toward inducible plastid gene expression may be valuable for basic research and for lab-scale expression studies, none of these systems is suitable for production-scale or field applications. Further improvements of the described systems and/or development of alternatives are required. Thus, inducible expression remains being a prominent challenge in plastid transformation technology.

2.6 Understanding Rubisco Function in Higher Plants for Improving Photosynthesis

Plants are remarkable factories: efficient green assembly lines that convert inert atmospheric gas and water into complex chemical compounds using solar energy. The foundation of this feat is the capture of atmospheric carbon dioxide through specialized structures and then its integration into higher-order structures starting with Ribulose-1, 5-bisphosphate carboxylase/oxygenase (Rubisco). Rubisco is a unique chloroplast stromal enzyme that in higher plants is composed of eight plastid genome-derived large subunits and eight small subunits encoded in the nucleus and imported from the cytosol (Houtz and Portis, 2003). The efficiency of carbon dioxide fixation by Rubisco is negatively impacted by its oxygenase activity (Ogren, 2003). Although an efficient system, Rubisco is an attractive target for engineering added capacity to fix atmospheric carbon. At a time where man seeks to exploit the energy locked in organic bonds present in recent tissues rather than fossil fuels, and when alleged greenhouse gases may negatively shape climate change, research into

integration of more atmospheric carbon into usable forms is timely and important. Research endeavors to understand Rubisco action with an aim of improving it has been carried out mainly in tobacco. Most have involved suppression/deletion of individual subunits or expression of both native and heterologous subunits in the nuclear or plastid compartment.

In 1988, the first transgenic Rubisco mutant was reported (Rodermeil *et al.*, 1988). This transgenic tobacco mutant was generated to understand coordinated expression of nuclear and organellar genes in the biosynthesis of Rubisco. The mutant is severely depleted in photosynthesis and Rubisco enzyme has been extensively studied to understand the role of the small subunit and the impact of Rubisco depletion on photosynthesis and carbon–nitrogen flux, as well as plant growth and development (Hudson *et al.*, 1992; Jiang and Rodermeil, 1995; Fritz *et al.*, 2006).

Most experiments pertaining to Rubisco engineering described so far have attempted to establish an experimental system to assemble a chimeric Rubisco. One of the strategies employed for engineering of Rubisco was to relocate the large subunit to the nuclear genome (Kanevski *et al.*, 1999). Transgenic tobacco plants were generated where the plastid resident large subunit was deleted using plastid transformation. This transgenic mutant plant was used as a host to engineer the large subunit in the nuclear genome. Although expression of the large subunit in the nucleus and its subsequent import into the chloroplast was normal, Rubisco enzyme content and activity were approximately 10% and 3% of the wild-type levels. Thus, the transgenic plants were severely depleted in Rubisco enzyme and its activity (Kanevski *et al.*, 1999). Experimental simulations predict that Rubisco derived from the photosynthetic bacteria *Chromatium vinosum* should exhibit superior performance compared to higher plant Rubisco (Bainbridge *et al.*, 1995). With this premise, the large subunit gene derived from *C. vinosum* was engineered in the nuclear genome of Rubisco deficient tobacco mutant SP25. The bacterial large subunit gene was transcribed in the cytosol but no large subunits or Rubisco activity was detectable (Madgwick *et al.*, 2002). From the preceding reports one can discern that integration and allotopic expression of the large subunit of Rubisco is possible but functionality

remains a problem. One can only speculate on the reasons for this failure. Post-translational modifications, import or different codon bias of the introduced genes may be responsible for lack of functionality.

Plastid transformation is routinely performed in tobacco (Dhingra and Daniell, 2006). As an alternate approach, plastid transformation was employed to express heterologous or native subunits of Rubisco in the plastid genome of tobacco. The native *rbcL* gene in tobacco was replaced via homologous recombination with the *rbcL* gene derived from *Synechococcus* or *Helianthus annuus*. Chloroplast transgenic tobacco plants expressing the algal *rbcL* gene lacked photoautotrophic growth and the large subunit protein was completely absent. Plants expressing the *Helianthus rbcL* gene were compromised in growth, as the carboxylase activity of the hybrid Rubisco was 20% of the wild-type levels (Kanevski *et al.*, 1999). Other reports have attempted to engineer Rubisco genes from algae that exhibit superior enzymatic properties relative to the higher plant enzyme. In these instances, Rubisco is produced from a dicistronic unit comprised of the large and small subunit gene. Expression of *rbcLS* operons from the rhodophyte *Galdieria sulphuraria* and the diatom *Phaeodactylum tri-cornutum* resulted in abundant foreign Rubisco expression but enzyme assembly remained an issue (Whitney *et al.*, 2001). Perhaps the assembly machinery is specific to the native subunits; thus foreign subunits remain unassembled or incorrectly assembled. A homodimeric form of the Rubisco encoding gene *RbcM* derived from proteobacterium, *Rhodospirillum rubrum* was integrated into the chloroplast genome of tobacco replacing the native *rbcL* gene. This enzyme is unique as it has no small subunit and thus has no assembly issues for activity. Growth of transgenic tobacco plants was supported in carbon dioxide enriched atmosphere and the catalytic properties were similar to the algal enzyme (Whitney and Andrews, 2001b, 2003).

The native tobacco small subunit gene has also been integrated into its own plastid genome. A His-tagged version of the *RbcS* gene was introduced into the wild-type background. A very low level of plastid-derived small subunit protein was detected (~1% of total small subunit protein) in the chloroplasts of transgenic plants (Whitney

and Andrews, 2001a). This continuum of reports reveals the lack of a system to appropriately express and assemble chimeric Rubisco proteins. One recent report used a creative approach of using the antisense *RbcS* tobacco plant to engineer the small subunit gene in the plastid genome. Although the introduced *RbcS* gene was well expressed it was not able to complement the deficiencies generated due to silencing of the small subunit (Zhang *et al.*, 2002). Importantly, this report became a prelude to the successful demonstration of a functional chloroplast-derived Rubisco in a following report. The plastid genome of the *RbcS* antisense mutant was used as a host to express tobacco *RbcS* gene with enhanced translation (Dhingra *et al.*, 2004). From this report it seemed that translation was a limiting factor that was overcome by the use of specific 5' and 3' untranslated regions that have been previously shown to result in improved expression of chloroplast expressed genes (Eibl *et al.*, 1999). The report by Dhingra *et al.* (2004) demonstrated that it was feasible to assemble Rubisco entirely in the chloroplast but it remains to be seen if heterologous subunits will be efficiently assembled using the expression enhancements that were described.

3. CONCLUSIONS

Twenty-five years ago tobacco was a rapidly regenerating system stemming from a crop with economic impact that is closely related to other high value crops. For these reasons it was held up as the system of choice for pilot transformation studies of both the nucleus and plastid. Upon review of the literature it is clear that these original studies set a stage for the flurry of work soon to follow in *Arabidopsis*—a laboratory-scale system with easier transformation, a smaller genome, and much faster life cycle. Recent studies in *N. benthamiana* have brought the genus back to the limelight as an outstanding system for transient protein expression. Overall, it is always important to understand the utility of this system, its advantages and limitations, as it still may be relevant to facets of discovery in plant biology. As a nonfood and nonfeed crop tobacco retains a remarkable potential for use as a biofactory. Ironically, this genus with a notorious health

reputation may prove to be indispensable for the production of medically relevant compounds.

1. INTRODUCTION

1.1 History, Origin, and Economic Importance

Coffee is one of the world's most valuable export commodities, ranking second on the world market after petroleum products. The total retail sales value exceeded US \$70 billion in 2003 and about 125 million people depend on coffee for their livelihood in Latin America, Africa, and Asia (Osorio, 2002). Commercial production relies on two species, *Coffea arabica* L. and *Coffea canephora* Pierre. The cup quality (low caffeine content and fine aroma) of *C. arabica* makes it by far the most important species, representing 70% of the world production.

C. arabica has its primary center of genetic diversity in the highlands of southwest Ethiopia and the Boma Plateau of Sudan. Wild populations of *C. arabica* have also been reported in Mount Imatong (Sudan) and Mount Marsabit (Kenya) (Thomas, 1942; Anthony *et al.*, 1987). Cultivation of *C. arabica* started in southwestern Ethiopia about 1500 years ago (Wellman, 1961). Modern coffee cultivars are derived from two base populations, known as Typica and Bourbon, which were spread worldwide in the 18th century.

Historical data indicate that these populations were composed of progenies of very few plants, i.e., only one for the Typica population (Chevalier and Dagron, 1928) and the few plants that were introduced to the Bourbon Island (now Reunion) in 1715 and 1718 for the Bourbon population (Haarer, 1956).

1.2 Botanical Description

Coffee species belong to the Rubiaceae family, one of the largest tropical angiosperm families. Variations in cpDNA classified the Coffeae tribe into the Ixoroideae monophyletic subfamily, close to Gardenieae, Pavetteae, and Vanguerieae (Bremer and Jansen, 1991). Two genera, *Coffea* L. and *Psilanthus* Hook. f., were distinguished on the basis of flowering and flower criteria (Bridson, 1982). Each genus was divided into two subgenera based on growth habit (monopodial vs. sympodial development) and type of inflorescence (axillary vs. terminal flowers). All species are perennial woody bushes or trees in intertropical forests of Africa and Madagascar for the *Coffea* genus, and Africa, Southeast Asia, and Oceania for the *Psilanthus* genus. More than 103 *Coffea* species have been described so far and about 70%
